In GAs, the initial population is selected on a random basis through which the final population (representing a solution to the problem) is obtained. The individual element of population is named as chromosome. In the later stage, the chromosomes are selected based on the fitness value and roulette wheel selection-based approach (Maulik and Bandyopadhyay 2000). The selected chromosomes are encoded using corresponding encoding techniques such as binary encoding (Xue et al. 2010). The binary string with p bits has p crossover points. The crossover points for the bit strings are selected randomly and the bit strings are mutated at the crossover points such that the overall fitness value is maximum (Yang 2007). The procedure is repeated for I iterations such that the maximum fitness value is obtained by convergence to an optimal solution in N -dimensional feature space (Forrest 1996). The overall fitness computation is implemented through the process of selection, crossover, and mutation for a maximum number of iterations. The best chromosome that lasts till the end is the solution to the clustering problem. The generations with best strings are preserved to produce maximum fitness function value. In this study, the application of genetic algorithm for data clustering is presented with an example.

GAs for Clustering

Clustering of samples in N -dimensional feature space is implemented as given in Fig. 2. In Fig. 2, the input data is pre-processed to overcome the problems like missing values and redundant features. In the second stage, clustering algorithm is selected to obtain the clusters in the data. The

Genetic Algorithms, Fig. 1 Implementation steps of GAs. GAs start with a selection of the initial population, encoding each chromosome of population into binary format, evaluating the fitness value of each chromosome, selection of crossover, mutating the chromosomes to obtain maximum fitness value, and repeating the steps until the best solution is obtained

Genetic Algorithms, Fig. 2 Methodology of implementing clustering technique. Collection of data, preprocessing of data, selecting clustering method, obtaining the initial clusters, evaluating the method, labeling the patterns, and training and testing the classification model

resultant samples in each cluster are labeled by the domain-specific expert knowledge. Let N be the size of dataset with each sample P having n features. The pattern P_i with n features is given as

$$P_i = [f_1 \ f_2 \ \cdots \ f_n].$$

The clustering problem is defined as grouping N patterns in the dataset to k clusters such that the intercluster distances are minimum. The intercluster distance of S patterns of cluster (P) from the cluster center (C_p) is

$$D_p = \frac{1}{s} \sum_{i=1}^s (C_p - P_i)^2 \quad (1)$$

The summation of k intercluster distances is

$$D = \sum_{i=1}^k D_i \quad (2)$$

The clustering algorithm with minimum D value is considered the best clustering algorithm to group the pixels in the dataset.

GAs provide better cluster centers, unlike the K-means, where the initial clusters are selected on a random basis. This is because GAs avoid converging to local minima unlike the K-means algorithm. GAs provide the optimal cluster centers when the number of training iterations reaches almost nearby infinity. The steps involved in implementing GAs for clustering are given in Fig. 1. In the first stage, the initial population is selected randomly such that each element of the population forms one cluster center. The population in GAs is equal to the number of clusters, i.e., if the number of clusters is equal to k , then the population is k (with k chromosomes in the population). The number of elements in each chromosome is equal to the number of features in the pattern (Nguyen 2015). Each chromosome in the population is encoded using various encoding techniques. In the next stage, the fitness value of each chromosome is computed based on the fitness function. The overall fitness function for clustering is.

$$F = 1/D. \quad (3)$$

The chromosomes are selected based on fitness value. Furthermore, the selected chromosomes are mutated at the respective crossover points. The procedure is implemented for a number of iterations and converges after reaching the efficient cluster centers (satisfying Eq. (3)).

Example

In this study, the performance of GAs in clustering the data has been evaluated with the IRS LISS III dataset of the Visakhapatnam region, India. The dataset consists of 400 samples without class label. Each pattern in the dataset is characterized by four features (four spectral bands such as bands-4), and 400 pixels are projected into 2D feature space. The distribution of 400 pixels in the bands 1 and 2 feature space is given in Fig. 3a. Two cluster centers generated using GAs are shown in Fig. 3b.

The initial population is considered with two chromosomes such that each chromosome represents a randomly selected cluster center. These chromosomes are encoded into binary sequences to form binary coded chromosomes. The initial population for the dataset is the randomly generated cluster centers in the N -dimensional features. The details of a randomly generated initial population for the present dataset are given in Table 1.

In Table 1, the initial population is generated with two chromosomes representing two cluster centers. Each chromosome consists of four elements representing four features in the dataset. The fitness value (D) of each chromosome is computed, and the chromosome with maximum D value is selected for crossover and mutation. The process is repeated for multiple number of iterations. The final population

Genetic Algorithms, Fig. 3 (a) Distribution of 400 samples in band 1 and 2 feature space. (b) Two cluster centers were generated using GA in the dataset. (c) IRS LISS III image with five clusters (namely, classes 1–5) (Visakhapatnam, India)

Genetic Algorithms, Table 1 Initial population (randomly selected) and final population (obtained after training for 50 iterations)

Population type	Chromosomes
Initial population	60 40 32 28 80 70 48 74
Final population	65 45 25 32 75 61 42 70

Genetic Algorithms, Table 2 Fitness value (D) of the K-means and GAs for a population of 5 is between 3.284 and 5.826; fitness value for GAs is between 3.544 and 3.845 for randomly selected initial population

Population	K-means	GAs
1	3.284	3.845
2	4.524	3.756
3	5.826	3.645
4	3.457	3.673
5	4.321	3.544

contributing to the maximum D value provides efficient cluster centers. In this study, the final population obtained after 50 iterations is given in Table 1. The final population representing the two cluster centers is given in Table 1. The D value obtained with GAs for five different randomly selected initial populations is given in Table 2. In all the five cases with various randomly selected initial populations, GAs produced maximum fitness value and converged to same D value. The convergence of GAs to maximum D value is better than the K-means clustering algorithm as the K-means produced different D values for different instances of initial population. The D values obtained by using GAs and K-means with the present dataset are given in Table 2. The fitness value for GAs is a maximum value of 3.943 in all the five cases while the fitness value of the K-means algorithm is varying between 3.284 and 5.826. The D value with GAs is almost the equal for all the five cases, indicating that in spite of randomly selected cluster centers, GAs produced optimum solution in all the five cases after 50 iterations. The two cluster centers obtained for the present dataset are given in Fig. 3b. The GAs were applied on a large-scale remote sensing image of Visakhapatnam region, India, and the resultant image is given in Fig. 3c. In Fig. 3c, the objects in the image are grouped into five clusters. Furthermore, the number of clusters can be increased to obtain the finite-level information in the images. The image obtained after unsupervised classification is labeled by the field expert. The labeled dataset is used to train classification model, and later, the trained model is used to classify multiple images. Recently, the classification models such as neural networks and deep neural networks have been used to classify large-size images.

Conclusion

In this study, the application of GAs for unsupervised classification is presented with example dataset. GAs were used to obtain the cluster centers for the unlabeled dataset. GAs provided an optimum solution with a randomized search approach. The optimized solution search is implemented through the principles and parallelism of evolution and natural genetics. The implementation steps of GAs such as selection of the population, evaluation of fitness, defining crossover, mutation, and converging to the optimal solution were discussed in this study. The performance of GAs was compared with the K-means algorithm in obtaining appropriate clusters in the unlabeled dataset. GAs with maximum fitness value outperformed the K-means algorithm in obtaining better clusters with remote sensing dataset. Furthermore, GAs provide better clusters in higher-dimensional remote sensing images.

Synonyms

Computational geosciences; Computational geophysics

Definition

Geocomputing denotes the use of computer simulation in the field of geosciences, especially in geophysics, to test hypotheses, perform parameter studies, or generate models of planetary interiors. Classical examples include the simulation of seismic wave propagation, porous media flow in reservoir studies, convection in the Earth's mantle, and the geodynamo. Such computational experiments require mathematical-physical equations to describe the system under consideration, numerical

algorithms to determine approximate solutions of these equations, and software implementing the latter such that the simulation can be executed on a computer. In order for the computational experiments to not only return qualitative but also quantitative results, measurements from the rich collection of geophysical datasets (e.g., plate velocities, seismic travel times, or gravity data) are incorporated into the simulations. The large and varied temporal and spatial scales involved in many geophysical questions make simulations often computationally very expensive: For example, capturing a rising plume or subducting slab in a global model of convection in the Earth's mantle might, at least locally, require a resolution of only a few kilometers. Many scenarios, thus, necessitate the use of mid- to extreme-scale parallel supercomputers.

The Why and How

The study of problems in solid earth is complicated by two facts. Firstly, the object under consideration is mostly inaccessible to direct measurements. While for near-surface problems, such as, e.g., determining underground porosity in reservoir engineering, drilling allows to perform sampling on a coarse scale; this is not feasible for most of the interior of our planet. Secondly, performing adequate laboratory experiments is difficult. While mineralogical experimentalists strive to at least partially recreate the enormous pressures and temperatures acting inside Earth, specimen sizes and time scales are vastly different. The same holds for the enormous forces involved in earthquake fracture processes.

Consequently, scientists in the field of geophysics often need to work with indirect observations, i.e., quantities which can be observed on or above the planet's surface and are proxies for internal dynamic processes or the composition of its deeper regions. Examples are measurements of travel times of seismic waves excited by earthquakes, influenced by the material the wave traversed in its path, changes in the Geoid and dynamic topography resulting from convection in the mantle, and associated mass movement or GPS measurements of plate motion.

Observational data alone, however, are insufficient to gain insight. Mathematical models are crucial to connect observations to underlying physics in order to interpret them and extract information. An example would be the comparison of Earth's normal modes to the theoretical model of an ideal ball. The first step is to define the correct equations to use for the model and to decide which effects are important, and which ones can be neglected. Most models in the geosciences involve partial differential equations (PDEs), such as the seismic wave equation in tomography, or the magnetohydrodynamic equations for the geodynamo. Thus, one needs to complement the equations by associated initial and boundary conditions.

After modeling one would like to evaluate the equations for the given data. However, only in the simplest of cases can one find a closed-form analytical solution of the problem. Alternatively, one can resort to numerical techniques from applied mathematics to determine an approximation of the unknown solution. This starts with a process denoted as discretization. It involves replacing the continuous domain, e.g., the Earth's interior, by a discrete computational mesh composed of simple geometric elements, such as tetrahedra or hexahedra. The details of the next step depend on the selected technique, commonly either the method of finite differences, finite volumes, or finite elements. In the former the differentials in the equations are replaced by difference quotients based on the mesh size, while in the latter the unknown analytical solution is approximated by a function from a finite dimensional space, such as piecewise polynomials defined for each element. In all cases the discretization leads to a linear or nonlinear system of equations which needs to be solved to determine the unknowns in the approximate so-called discrete solution. Additionally, as most problems involve time, one also needs to perform discretization of this extra dimension. Usually this involves some form of time-stepping, i.e., one starts from the initial conditions and successively computes approximate solutions at discrete points in time, using previous ones already available.

In order for the discrete solution to be reasonably close to the exact solution, spatial meshes need to be quite fine and time-step sizes need to be small. This results in a large number of degrees of freedom in the system of equations which must be solved for numerously in the time-stepping. Consequently, this cannot be done manually but requires the use of a computer. For this, the numerical algorithms must be implemented in a software program. Once such a simulation was run, its results can be post-processed, e.g., visualized, to allow their interpretation.

Many problems of interest in the solid earth, such as seismic wave propagation, global seismic tomography, earthquake fracture dynamics, convection of the Earth's mantle, reservoir simulations, or the geodynamo, involve spatial and/or temporal scales that require such high resolution that the resulting models fall into the realm of high-performance computing (HPC), (Hager and Weller 2011), and can only be simulated on large-scale parallel supercomputers. In fact such simulations have traditionally been key consumers of CPU hours at academic and industrial supercomputing centers, next to other applications from meteorology, computational chemistry, or astronomy. From 2002–2018, Japan even operated a series of supercomputers termed “Earth Simulator”, dedicated primarily to climate and solid earth physics simulations.

The approach described above is generally referred to as scientific computing or computational science. It can be seen as performing virtual experiments on a computer. It has

significantly gained in importance in the last decades and joined theory and experiment as a third pillar of scientific discovery, see (Gustafsson 2018).

Selected Applications and Challenges

Studying mantle convection is essential to our understanding of how the entire planet works, as the heat transported from deep within our planet to the surface is responsible for most of the geologic activity of Earth. Numerical simulations are an important tool to obtain a quantitative understanding of buoyancy forces in the mantle. Knowledge of these forces is a prerequisite for correctly modeling lithosphere dynamics and tectonic processes. Mantle flow also affects the geodynamo, the process generating Earth's magnetic field. The time scales of geologic processes, on the order of millions to hundreds of millions of years, are sufficiently long that the mantle can be treated as a fluid, although being capable of transmitting seismic shear waves on time scales of seismic waves (seconds to hours). Mantle convection is therefore governed by the equations of motion of a viscous fluid (i.e., the hydrodynamic field equations) expressing the fundamental principles of mass, momentum, and energy conservation. A forward simulation requires physical input parameters for thermal conductivity and expansion, viscosity, specific heat capacity, etc. An equation of state relating density to pressure and temperature is furthermore required to be able to solve this system of coupled PDEs.

The material properties and the energy input (radioactive heating and heat flux from the core) determine the vigor of convection. Owing to the high viscosity of mantle rock, inertial forces are small (Reynolds number $\mathcal{O}(10^{-21})$) and can be neglected in the momentum equation together with Coriolis forces resulting in an instantaneous force balance between viscous resistance and buoyancy, which is referred to as Stokes flow. Once a set of parameters is chosen, a unique solution to the mantle convection equations can be computed given that an initial condition for temperature and boundary conditions for both temperature and flow velocities are provided. Specific nonzero Dirichlet velocity boundary conditions taken from plate tectonic reconstructions can be applied for Earth's surface. Through this sequential data assimilation, a geologically informed prediction of the present-day flow velocities and temperature field in the mantle is obtained.

Such models with earth-like physical parameters require numerous time-steps and extremely fine meshes (~ 1 km resolution at least locally), and models with over 10^9 degrees of freedom can be simulated on large-scale supercomputers, (Bauer et al. 2020; Johann et al. 2015). The past three decades have seen great progress in the adoption of modern numerical techniques and their application in this field. Today a number of powerful software packages exists that allow to simulate

mantle flow in a 3D spherical shell geometry on a global scale on a routinely basis on HPC systems, (Heister et al. 2017).

In these codes the mantle is approximated as a thick spherical shell, which is typically discretized by using either an icosahedral grid, a (modified) cubed sphere, or a yin-yang grid, (Bauer et al. 2020; Ismail-Zadeh and Tackley 2010), and adaptive mesh refinement might be employed. Due to their flexibility, e.g., in incorporating strong parameter variations, and their relaxed smoothness requirements as opposed to finite differences, finite elements are currently the preferred choice for discretizing the hydrodynamic equations. In the resulting discrete equations, it is the solution of the generalized Stokes problem for velocity and pressure one or multiple times per time-step that is the dominating cost factor. For this one relies on iterative solvers, mostly combinations of Krylov subspace methods with multigrid techniques, (Bauer et al. 2020; Ismail-Zadeh and Tackley 2010). For more details on the mathematical and numerical treatment of mantle convection see, e.g., (Ismail-Zadeh and Tackley 2010).

As mantle convection evolves over time scales of millions of years, any testing of predictions for future mantle states is infeasible. While the present-day thermodynamic state of the mantle can be estimated from seismic tomographic models, initial conditions in the past needed for a corresponding forward simulation are unknown. This, however, can be formulated as an inverse problem. Here, one iteratively optimizes the initial condition in the geologic past based on the current, terminal, state of the mantle. Technically this relies on adjoint formulations to compute the gradient of the target functional. Comparing the results of such retrodictions against geologic evidence provides crucial insight into mantle behavior.

Current challenges in these geodynamic simulations are the huge computational costs for the retrodictions, as they involve multiple forward simulations, and the trend to include complex physical phenomena such as rock compressibility or nonlinear deformation laws into models.

In computational seismology, (Igel 2016), the physics-based forward modeling of the PDEs describing the short-time behavior of elastic solids advanced over the last decades to routinely simulate wave propagation in strongly heterogeneous and complex media (Fig. 1). Taking into account the full 3D complexity of ground motion improves forecasting of strong earthquake-related ground shaking and provides continuously sharper images of Earth's interior via tomography. Since the early 1970s a variety of numerical methods including finite difference, boundary integral, boundary element, pseudo-spectral, finite element, finite volume, discontinuous Galerkin, and spectral element methods were used to demonstrate complex source, path, and site effects on ground motions.

Among these, the spectral element method (SEM) established itself as one of the favored methods for global

Geocomputing,

Fig. 1 Snapshots of the seismic wavefield from a multi-physics simulation using the present-day 3D structure derived from a mantle convection model. 3D global seismic wave propagation was simulated for an earthquake in the Fiji Islands region, (Schuberth et al. 2012). Green and magenta colors depict the wavefield, while shear wave velocity variations in the model are visualized by vertical cross-sections and isosurfaces on a blue to brownish color scale. and regional computational seismology applications (Komatitsch and Vilotte 1998). It is based on a weak formulation of the PDE. This allows to naturally handle both, interfaces and free boundary conditions, yielding very accurate resolution of evanescent interface and surface waves –

phenomena of major importance in seismology. Unknowns are approximated by continuous functions composed of high-order piecewise polynomials. The SEM attains its efficiency from a tensor product representation of these polynomials on hexahedral meshes and a combination of interpolation and

integration points that results in a diagonal mass matrix, which can trivially be inverted in the context of explicit time integrators.

Recently, Discontinuous Galerkin (DG) methods have become a widespread choice for large-scale simulation of hyperbolic problems. DG allows to use meshes composed of triangles and tetrahedra which simplifies meshing of complex geological structures or complex topography, such as volcanoes, sedimentary basins, fault zones, geological interfaces, and sharp impedance contrasts. Further advantages include low numerical dispersion as well as the easy and efficient implementation of local time-stepping. Their use of numerical fluxes allows to naturally include nonlinear interface conditions, arising, e.g., in dynamic earthquake rupture problems, while combination with an arbitrary high-order derivative (ADER) time integrator allows high-order accuracy in time within a single-step scheme.

Understanding the dynamics of earthquakes and faults poses a multiscale, multi-physics problem with profound societal implications, such as secondary effects with unforeseen hazard complexity (Fig. 2). Earthquakes can be represented as frictional shear fracture of brittle solids under compression along internal boundaries of preexisting weak fault interfaces. During the highly nonlinear interaction of frictional failure and seismic wave propagation computational models may, in addition, include multi-physics processes like off-fault deformation or thermal pressurization of rock pore fluids. DG methods have been particularly impactful in this context having the potential to overcome the limitations of short-term (incomplete) earthquake data by incorporating field data and laboratory measured rock behavior.

High-resolution earthquake shaking and rupture modeling based on elastodynamics has been advanced significantly by, and in turn contributed to, large-scale HPC. Recent computational advances now allow to capture nonlinear rupture dynamics on complex faults or fault systems (Fig. 2) up to the scale of megathrust events and on extreme-scale supercomputers (Uphoff et al. 2017).

HPC-empowered computational seismology and earthquake modeling is a key tool to better understand the structure of Earth's interior and sources of seismic energy. It is becoming an important part of the rapid earthquake response toolset by delivering physics-driven interpretations that can be integrated synergistically with data-driven efforts. Ongoing challenges include computational efficiency (resolving smaller-scale heterogeneities affecting the high frequencies of the wave field), addressing model sensitivities and the need for community solutions. Combination with emerging machine learning approaches may close the gap of data quality in real-time conditions, boosting our understanding of earthquake source processes and the associated ground shaking.

Conclusions

We demonstrated that the application of scientific computing to geoscientific problems, denoted as geocomputing, is of major importance in this field. Two challenges are the constant strive to get simulations closer to reality, leading to more sophisticated but also more costly computational models and that many problems of interest can only be simulated on supercomputers.

Geographical Information Science

Parvatham Venkatachalam

Centre of Studies in Resources Engineering, Indian Institute of Technology, Mumbai, India

Definition

Geographical Information Science (GISc) is a scientific research discipline that provides the technology to handle large volumes of spatial data derived from a variety of sources, study the characteristics and relationships in the data, model, analyze, and provide the development strategies as per the user defined requirements. GISc has evolved over the past six decades generating massive interest worldwide. GISc is the science behind the development of Geographical Information System (GIS) technology and GIS software tools. It provides a spatial framework to assist optimal use of natural resources. Developments in spatial data standards, interoperability, World Wide Web, and the availability of spatial data infrastructure are making GISc a core scientific area in resources management.

Introduction

Data are the raw figures collected from varied sources for specific purposes. When the data are structured, organized, processed, and presented to make them useful and relevant to a context, data gets converted into information. Information science deals with the study of data collection, classification, organization, storage, retrieval, analysis, and dissemination of information. Geographical Information Science (GISc) deals with the research study of geographical/spatial data. GISc is a multidisciplinary field and there has been a rapid development in GISc due to the contributions of experts from several disciplines such as geography, cartography, geodesy,

photogrammetry, mathematics, statistics, computer science, remote sensing, earth sciences, engineering fields, humanities, and social sciences (Fig. 1). Geographical Information Science operates through the techniques, methods, and approaches associated with GIS and seeks to redefine the geographical concepts and their use in the context of GIS (Viana et al. 2019). It focuses on spatial data collection, accuracy assessment, data models and structures for efficient storage, spatial relations inherent in the data, interpretation, modeling, analysis, and finally the visualization and presentation of the results for end user benefits. The components of GISc are shown in Fig. 2.

Geographical information science and the geospatial technology using digital platforms started in mid-1960s. But the manual methods of using qualitative maps for decision making existed centuries back. They used general purpose maps and thematic maps for various applications. During 1940s, use of statistical methods for spatial analysis started. With the availability of computer technology and the advent of remote sensing satellites and global positioning systems (GPS), GISc started evolving using digital spatial data in decision making. There is no strictly a logical progress or evolution toward the development of geospatial technology (Venkatachalam 2009). Initiatives were taken in different parts of the world by academia, government agencies, and industries to use computer technology for spatial data handling and analysis. With the introduction of internet, Internet of Things (IOT), drones, and high resolution satellites, spatial data are getting generated faster than they can be analyzed. Today millions of professionals use geospatial technology and it is playing a central role in e-government initiatives. Geospatial technology has become a part of information technology and provides enterprise solutions. This entry discusses briefly various components of GISc in the present scenario and the open research challenges in the field of geographical information science.

Spatial Data Concepts

Geography of the Earth varies continuously and is very complex to quantify digitally and bring it within distinct boundaries. To describe an area, key features existing in that area are identified simplifying the inherent complexity. The features get described as water body, built-up area, hilly terrain, or individual locations such as building, electrical pole, and so on. These geographical features are related to each other in terms of in the left, in front of, etc. These conceptual data get converted into digital form using spatial data models. We view the real world through this digital data base. To describe a school spatially, we give its location (Lat/Long) and its properties (name, address, number of students, etc.). Location

Geographical Information Science, Fig.1 A Multidisciplinary Field

Geographical Information Science, Fig. 2 Components of GISc

gives the spatial information and associated properties give its characteristics.

Spatial database contains digital information of real objects such as water bodies, roads, buildings represented as point features (buildings, line features (roads), and area features (lakes). Some features vary continuously on the Earth such as temperature, elevation, vegetation, etc. By dividing the study area into zones with the assumption that the feature is constant within each zone, measurements are taken at sample points within each zone. Also contours are prepared connecting points of equal value with lines.

A spatial entity (spatial object) is identified by a single identifier and it cannot be subdivided into like units. The spatial object can be a point/line/area feature. The indivisibility is based on the characteristics used to define the object and one cannot expect complete homogeneity within the spatial extent of the object. A spatial object is defined by an identifier (name), position on the Earth's surface (location), character, and function of the object and its spatial properties (Laurini and Thompson 1994). In general, spatial features are represented digitally in three ways. A point object has a position in space and it has no length and has zero dimension

(e.g., a building, a tower). A point can be a node or vertex. A line is a one-dimensional object and has the property length. A line has two end points and points in between to mark the shape of the spatial feature (e.g., road, contour). An area is a two-dimensional object and has the properties area and perimeter. An area can be alone or can share the boundaries with other areas. Existence of holes within an area (pond inside a village) means that the area has external and internal boundaries. An area is generally called as polygon.

Spatial features are represented as point or line or area depending on the scale of the original map source, the purpose of the study, and other factors. A city may be a point on a small scale map (1:250,000) and can be an area in a large scale map (1:25000). The map scale of the source document helps to decide the level of details to be stored in the spatial database.

A spatial database has location, spatial relationship with other data, attributes or the characteristics, and time wherever essential. The attributes are stored in a table where each spatial object corresponds to a row in the table and the attributes correspond to columns in the table. Temporal information can be stored by giving interval of time over which the object exists or giving values at certain points of time. Relationships between spatial objects can be defined in terms of proximity, distance, intersect, containment, touch, disjoint, etc. For example, a point object can be in north of another point object or can be on a line object or can be inside a polygon object. During spatial analysis, new objects can be generated from original objects. Area object can be transformed to point objects using centroid calculations. Thiessen polygons generate area objects from point objects.

The spatial database contains both spatial and attribute data. In a geospatial database, the spatial data is stored using vector or raster data structure in a file while attribute data is stored in a relational database. Unique ID given to each spatial object helps to link the spatial and attribute data. Most well-known GIS packages use the geo-relational database model. Some of the recent GIS tools try to store both spatial objects and attributes in a single relational table using object-relational model.

Spatial Data Sources

Spatial database is created collating data from variety of sources and is one of the most important parts in geospatial technology. It is an expensive task. Data comes from topographic sheets, surveyed maps, government records, and remote sensing data including satellite images, aerial photos, and drones. Plenty of data may be available in different agencies but accessibility, accuracy, and quality are important issues. Available and accessible data may not be in digital form. Presently, government departments globally are

working on creating spatial data warehouses with necessary metadata information. Open Geospatial Consortium (OGC) regularly brings out spatial data standards and data exchange formats so that interoperability becomes feasible at the user end. Based on the time, cost, and scale of problem, one can generate spatial data from primary sources or collate from secondary sources.

Remote sensing data is one of the main sources for primary data generation. With the availability of high resolution images from satellites, air platforms, and drones, very detailed spatial information can be generated. They also help in updating old thematic information. Digital orthophotos help in extraction of elevation data with improved vertical resolution. In addition, field survey helps to collect primary data (e.g., soil, geology, etc). Global Positioning System (GPS) is a common affordable tool for getting geographical location and elevation information. Secondary data sources are the national survey departments and they provide topographic sheets, thematic maps, and census data on demography, socioeconomic information, agriculture, etc.

When data are collated from different sources, we must know the scales of measurement used for numeric values. That determines the type of mathematical operations that can be performed on the data. The numerical values are defined with respect to nominal, ordinal, interval, and ratio scales of measurement. On nominal scale, numbers give identity while in ordinal scale, the values give the order (1st, 2nd, etc.). In interval scale, the differences between values are given and the scale does not start at zero. Hence, subtraction makes sense and not division. In ratio scale, measurement has an absolute zero and division makes sense.

Geographical Coordinate System

Even though the Earth appears flat at a closer look, it is relatively spherical. The geographical coordinate system (Latitude and Longitude) helps to specify quantitatively the location of any spatial feature on the Earth's surface. Latitudes are measured in degrees toward north or south from equatorial plane starting from 0° to 90° . Longitudes are measured in degrees toward east or west from Greenwich starting from 0° to 180° . Using these coordinates, distances and areas are calculated using spherical geometry and radius of the Earth. Lines connecting points of same longitude are called meridians. The prime meridian passes through Greenwich, England, and referred as 0° meridian. Lines connecting points of same latitude are called parallels. Any two parallels are always the same distance apart. Meridians are farthest apart at the equator and converge to a single point at the pole. Parallels and meridians cross one another at right angles.

The Earth is not a perfect sphere. It is wider along the equator than the poles. Hence it is approximated to an

ellipsoid and the difference between the major axis (along the equator) and the minor axis connecting the poles is approximately 21 kms. As the Earth has surface irregularities, an ellipsoid that fits to one region or country is chosen as the ellipsoid for that region. When an ellipsoid approximates the shape of the Earth, a datum defines the position of the ellipsoid relative to the center of the Earth. Many countries have their own datums. An earth-centered (geocentric) datum using the Earth's center of mass as the origin is the most widely used datum known as WGS84 (World Geodetic System 1984). While doing spatial data analysis, all data layers must be on the same reference datum.

The vertical datum is used while measuring elevation. GPS gives elevation from the ellipsoidal surface. A geoid is a closer approximation of the Earth, which is considered as the mean sea level in that region. In order to get elevation from mean sea level (geodetic) of a land feature, the difference between the geoid surface and the ellipsoid surface must be measured locally.

A scale of a map is the ratio of the map distance to the ground distance. A 1:2500 scale map means a map distance of 1 cm on the map represents 2500 cms on the ground. Generally a 1:2500 scale map is called larger scale map and 1:250,000 scale map is called small scale map as a 1:2500 scale map gives more details corresponding to a smaller area compared to 1:250,000 scale map.

Map Projections

A set of mathematical techniques are developed to project 3-dimensional spherical surface of the Earth on a 2-dimensional planar surface, which are called map projections. The projected map gives a systematic arrangement of parallels and meridians on a plane. However, the map projection involves distortion in terms of shape, area, and distance and no map projection is perfect. Every map projection preserves certain spatial properties while sacrificing other properties. Choice of a map projection depends on the purpose of the map, type of area covered, extent, location, properties to be preserved, needed accuracy, etc. Map projections are of three types: conformal, equivalent, and equidistant. A conformal projection preserves local angles and shapes while an equivalent projection preserves areas. An equidistant projection preserves distance in a direction or at a place.

The principle of map projection is by keeping a light source inside a globe and projecting the spatial features of the globe onto a 2-dimensional surface surrounding the globe. A cylinder, a cone, or a plane paper can be used as a projected surface. The process of projecting a spherical surface onto a projected medium is done using mathematical principles of geometry and trigonometry. All projections are grouped as cylindrical projections, conical projections, and azimuthal

projections. The orientation of a projection surface can be changed as needed. A cylinder is normally oriented tangent along the equator and a cone is normally oriented tangent along a parallel. A plane is normally oriented tangent at the pole. If the projection surface is changed to 90° from normal, the result is a transverse projection. If the projection surface is at an angle between the normal and transverse position, the result is an oblique projection. The line of tangency between a projection surface and the globe surface is called standard line and there is no distortion on that line. When the projection surface intersects the globe, the result is a secant projection with two standard parallels. In the case of azimuthal projection, the light source can be at the center of the globe or at the opposite pole or from infinite position.

To get the coordinates on a projected map, the midpoint of the central parallel and central meridian becomes the origin of the coordinate system and the coordinates are calculated as per four quadrants. As the map is generally oriented toward north, x-value in the east direction is called easting and y-value in the north direction is called northing. The most well-known projection globally is the Universal Transverse Mercator (UTM) projection. It uses varied cylinders with different central meridians for different zones to minimize the distortions. There are 60 zones, each zone covering 6° longitude and numbered sequentially starting with 1 at 180° W and moving toward east. Each zone is further divided into north and south hemispheres.

Spatial Data Models

The continuous geographical variations of the real world have to be approximated and abstracted for converting them into quantitative or digital form in finite dimensional space. A spatial data model converts these variations into discrete objects. A spatial data model gives a set of rules for representing spatial objects and the spatial relations between them. Two major spatial data models are raster data model and vector data model. A geographical space can be considered as a container of a series of thematic map layers such as land use, drainage, topography, soils, administrative boundaries, etc. The spatial objects can be categorized into points, lines, and areas. Points represent features such as schools, buildings, wells, electric poles, etc. while lines represent roads, topographic contours (lines connecting points of equal heights), drainage, etc. Area features can be water bodies, land use boundaries, administrative boundaries, etc.

In a raster data model, grid is a unit and the value in each grid gives the characteristic of the spatial feature in that grid. A raster data layer has rows, columns, and grid values. Grids are also known as pixels. Well known examples are remote sensing images and scanned maps. A raster layer is a matrix with rows and columns and grid values are stored in

2-dimensional array. Each grid in the raster model is intrinsically related to other grids in terms of row and column position. Hence spatial relations are explicit and inbuilt in raster data model. Point features are shown by single grids, line features are shown by a sequence of neighboring grids, and area features by a cluster of contiguous grids. The grid value can be binary, byte, or integer or a real value based on the theme it represents. The grid size gives the resolution of the raster data. If the grid resolution is smaller, data accuracy will be better. However, the data volume and processing time will increase. Remote sensing images and digital elevation models (DEMs) use raster data structure and grid values continuously change to bring out high spatial variability. When spatial variability is not very high (e.g., village boundaries, land use), data compression methods are used to reduce the size of the data file. Well-known data compression methods are run-length encoding, value point coding, and quadtree. In a raster data layer, a header file gives metadata information, geographical coordinates of corners of the map layer, rows, columns, resolution, etc.

The vector data model helps in precise positioning of spatial features. The map layer is assumed to be in a continuous coordinate space and features are represented in terms of x,y coordinates in Cartesian coordinate system. A point feature is given by a single x,y coordinate pair, a line by a sequence of x,y coordinates, and area as a closed boundary of x,y coordinates. Along with spatial objects, corresponding attributes are stored in a separate table.

Initially, spaghetti model had been in use as vector data structure. A point is encoded as a single x,y coordinate and a line feature as a series of x,y coordinates with a start node and an end node. An area feature is treated as a polygon and is stored as a closed loop of x,y coordinates that defines its boundary. In spaghetti data structure, the common boundary between neighboring polygons is stored twice once for each polygon. The limitation in this data structure is that the spatial relationships among the spatial objects such as polygon inside a polygon or a polygon adjacent to another polygon are not getting encoded.

To overcome these limitations, topological data model has been adopted. Topology is the study of those properties of geometric objects that remain invariant under certain transformations such as enlarging, skewing, bending, stretching, etc. Basic entity in this model is an arc (a series of x,y coordinates) with a start and end node. In the case of network data such as road network, for each arc along with its own arc ID, the connecting arcs' IDs on both of its ends are also stored. Also the minimum bounding rectangle (MBR) for each arc gets stored to assist in query search. In the case of polygon data, along with each arc, the IDs of the polygons which fall on the right side and left side of the arc get stored. This avoids duplication of common boundary between polygons and at the same time, query such as adjacency can be

done easily. It also helps to store polygons inside polygons or nested polygons.

The topological data model helps to store efficiently each polygon, its area, perimeter, minimum bounding rectangles (MBRs), and polygons inside polygons efficiently. In addition to points, lines and polygons, regions and routes can also be stored in vector data structure. A region is a cluster of polygons with uniform characteristics and the polygons can be joint or disjoint. Example is a group of islands like Andaman and Nicobar islands that can be stored as a single spatial entity. Similarly, a route consists of many arcs like a highway or a stream. In vector data structure along with spatial objects, associated attributes are stored in suitable database packages.

Triangulated Irregular Network (TIN) is a topological model to represent terrain elevation data. It stores terrain surface as a set of nonoverlapping triangles with the assumption that each triangle has a constant gradient. Flat surface can be represented by fewer but larger size triangles while the terrain with high variability in elevation has to be represented by denser but smaller size triangles. From the irregularly sampled elevation points, a TIN data model is built using Delaunay Triangulation method. It uses the principle that the triangles have to be as equiangular as possible and the circumcircle of a triangle should not contain another sample point. This model helps to handle even features such as ridge lines, valleys, high peaks, etc. In TIN model, along with vertices, slope and aspect of each facet also get stored.

Spatial Database Creation

In any geospatial technology application project, around 75% of the cost goes in spatial database creation. It is a time taking, labor-intensive and error prone task. Many countries have started national spatial data warehouses, and users can download the data on payment or free of cost. As digital data may be in varied formats, global agencies are working on spatial data standards and interoperability among the datasets.

Generally, the original maps are in paper forms in different scales and projections. These maps have to be scanned, manually digitized (vectorized), cleaned, and edited to convert them to topological structured data. In order to bring all map layers of a study area (e.g., drainage, contours, land use, soils, forestry, administrative boundaries, etc.) to a common reference system, several transformations may have to be carried out such as projection and datum change, geometric transformation, etc.

In the first step, the paper maps are scanned using the best resolution feasible. Then vectorization of spatial features using on-screen digitization method is done manually or using semiautomatic method like line follower. Spatial data cleaning is an important step so that spatial relations can be built using topology. Several errors such as undershoots,

overshoots, duplicate arcs, and sliver polygons (generally obtuse angled thin elongated triangles) have to be removed. Many GIS packages provide automated methods to clean these errors using the tolerance limits given by the user.

Geometric transformation or geo-registration is a step to bring all thematic layers into a common reference system. This step is done in a similar way like in remote sensing and photogrammetry. Using a set of known control points (tic marks or ground control points) between the base map and slave map, a mathematical relation (a second/third order polynomial) is formed. Using that polynomial, the slave map gets transformed to base map coordinate system. In the case of transforming a satellite digital image to a raster map layer coordinate system, in addition to geometric transformation, pixel resampling has to be done using nearest neighbor or bilinear interpolation or cubic convolution method. In geospatial technology, in addition to spatial objects, the associated attributes (characteristics/ properties) have to be handled. Most of the GIS tools use relational database model to store attribute data either in a single table or multiple tables and link the corresponding spatial objects using unique IDs.

Spatial Relations

A spatial relation describes how an object is located in relation to another object in space based on geometric properties. In the case of geospatial science, it is used to describe the spatial relations among point, line, and polygon objects. There are three types of spatial relations, namely, topological, directional (cardinal), and distance (metric) relations. Directional relation specifies the direction where an object is located with respect to a reference object (e.g., left, right, north, south, etc.). Distance relation explains how far an object is located with respect to a reference object in terms of distance and angle. In addition, there can be spatial relations between objects in terms of morphology such as size, shape, and structure of the objects.

Topological relations are spatial relations that are invariant under topological transformations such as translation, rotation, and skewing (Egenhofer and Franzosa 1991). Topology helps to capture the most important spatial properties. Space can be defined as 0-dimensional (point), 1-dimensional (x-axis), 2-dimensional (x-y plane), and 3-dimensional (x-y-z volume) space. Similarly a spatial object can be defined as 0-dimensional object (a point), 1-dimensional (a line), 2-dimensional (a polygon), and 3-dimensional (a volume). The difference between the dimension of the embedding space and the dimension of the spatial object is called co-dimension. When a point is in a plane (a well in a village), the co-dimension is 2. Topological spatial relations are described based on the spatial object and the space where it is embedded. A spatial object A has 3 components: an interior

(A°), a boundary (∂A), and an exterior (A'). An example using 2 polygons (A and B) in a plane (R^2) is explained. The polygons A and B can be topologically related using the fundamental distinction of intersection: empty ($\emptyset$) and nonempty ($-\emptyset$). With 2 possibilities and 9 intersections (3×3), the number of possible topological relations is 2^9 and all the possible 9-intersection (9-i) matrices can be physically written. However, one cannot get a geometrical figure for each of those matrices. It depends on the type of the object and the type and the dimension of the embedding space. In the case of 2 polygons A and B in a plane (R^2), the eight spatial relations and the corresponding 9-i matrices in terms of $\emptyset$ and $-\emptyset$ are given below (Fig. 3).

Spatial Data Analysis

The data analysis is the main activity in geospatial technology. Based on the application, it can perform simple data retrieval to a complex modeling analysis. The method of analysis depends on the data model that has been used to represent spatial data.

Vector Data Analysis

In vector data model, the attributes of spatial objects are stored in a database. The simplest analysis function is to run a query in attribute database and show the results both in tabular form and the corresponding spatial objects in a map form on the screen. The query can be a simple query on a single table or a complex query joining multiple tables. The query is given in SQL (structured query language) format. For example, highlight the villages in a district which have a population greater than 10,000 and a bank. Also using any attribute, density map can be generated. In these types of attribute analysis, existing spatial objects are used and no new spatial object is generated.

Under vector data operation, as spatial objects are stored in point, line, and polygon layers, the queries can be executed using two layers. The spatial operations can be categorized under union, intersect, identity, clip, update, erase, and split. All overlay methods are based on the Boolean connectors AND, OR, XOR (Chang 2009). For example union operation combines two layers and generates a new polygon layer with topology and a new attribute table. It is equivalent to the Boolean operation OR and is a spatial join operation. In addition to two layers operations, single layer operations such as buffer, eliminate, and dissolve can be done. Buffer operation helps to generate buffers of specific distances around a spatial object. Any complex spatial analysis can be made into a stepwise flow chart identifying suitable operations and can be executed using these capabilities. The

Geographical Information Science, Fig. 3 9-i Intersection Matrices for 2 Polygons in R^2

important aspect is that all layers must be brought to a common reference system before starting the analysis.

Raster Data Analysis

In raster data structure, regular grid pattern is used to cover the space and the value in each grid gives the characteristic of the spatial phenomena in that grid. In raster data analysis, operations are done on these grid values and the operations can be categorized as local, focal, and zonal operations.

In local operations, a new raster layer gets created from one or more input layers. The value of each new grid is computed using the values of the same grid of the input layers based on a mathematical or trigonometric or logarithmic function. In local operations, the neighboring or distant grid values of a layer have no effect. A well-known local operation is map algebra, which is similar to band algebra in digital image analysis of remote sensing data. In map algebra, the input

raster layers can be combined using various conditions involving algebraic, logical, and relational operators. In addition, under local operations, raster layers can be overlaid (similar to union in vector data model) and a new layer can be created.

In focal operations, a single input layer gives a new output layer and the grid values for the output layer are computed using the neighborhood of the grid values of the input layer. Similar to low pass/high pass filtering operation in image processing, filtering can be done on raster layer with a 3×3 or 5×5 moving window giving suitable weights. Another important utility is the generation of slope and aspect maps from the input layer of elevation values. Buffering, proximity maps (thiessen polygons), and distance mapping from a given facility can be carried out.

Zonal operation uses a zone (a group of grids that have the same value) map and a thematic map (rainfall, elevation, temperature, etc.). This operation computes the minimum, maximum, mean, standard deviation, etc., for each zone

based on the thematic data and generates a table giving the statistical parameters for each zone and also corresponding maps.

The raster data model uses a simple data structure and is very useful when multiple thematic layers have to be combined using various criteria. It is desirable to use raster data model for applications related to natural resources management. Vector data model is more suitable for network analysis such as shortest path finding, location-allocation problems, infrastructure planning, etc.

Spatial Data Interpolation

Very often, the data are available at few sample points and using a suitable algorithm, one has to estimate the values at other points in a study area. One of the examples is elevations data. Spatial interpolation methods use the data values at known points and estimate the values at other points. The principle behind these methods is that the points closer in space are more likely to have similar values than the points far apart. There are several spatial interpolation techniques used in spatial data science.

A global interpolation technique uses every known data point to estimate the values at other points. It results in a smooth surface. A local interpolation technique uses a small portion of known data points to estimate the values in nearby points. It brings out local variations. Exact interpolation methods preserve the values at known points while the approximate interpolation methods may get new values at known points. Some interpolation techniques are deterministic and some are stochastic, which help to assess the predicted errors.

Trend surface modeling is a global technique where a first-order (linear) or a second-order (quadratic) or a third-order (cubic) polynomial equation is formed using the data at known points. The resultant polynomial is used to calculate the data at unknown points.

A well-known method is Inverse distance Weighted (ICW) method where the estimated value of a point depends more on nearby points than far off points.

The general formula is

$$z = \left(\sum_{i=1}^n w_i z_i \right) / \left(\sum_{i=1}^n w_i \right)$$

where w is a function of distance such as $1/d^k$, z is the value to be estimated, z_i are the known values for n number of points, d_i is the distance between the i^{th} point and the point for which the value is estimated and k is a power. A variety of algorithms can be generated by changing the distance function w , varying

the number of sample points and changing the directions from where these sample points are selected.

Kriging is a spatial interpolation technique based on Geostatistics principles. The basis of this technique is the rate at which the variance between points changes over space. This is expressed in terms of variogram, which shows how the average difference between values at points changes with distance between points. Many kriging algorithms are available such as ordinary kriging, universal kriging, simple kriging, block kriging, etc. When the number of input sample points is high, kriging method becomes computationally intensive.

Digital Terrain Mapping

The terrain is a continuous surface with undulations, and digital terrain modeling helps to visualize this undulating terrain in a map form. Generally, digital terrain data is given by the elevation value (z) above the mean sea level at known points. In raster data model, z value gives the elevation of a grid while in vector data model, z value is given as an attribute for a point object or for a line object (e.g., contour). The representation of elevation in raster data model is called as digital elevation model (DEM) and in vector format it is known as Triangulated Irregular Network (TIN) model.

A digital elevation model is created using suitable spatial interpolation technique from the input of known elevation data at regularly or irregularly spaced points. Input data sources are field measurements using GPS, stereo images, digital contours, Radar, LIDAR data, etc. The quality of DEM depends on the spatial and vertical resolution of the input data. The quality of DEM influences the accuracy of the terrain measures such as slope, aspect, automatic delineation of drainage network, etc.

A Triangulate Irregular Network represents the terrain data with a series of nonoverlapping triangles. There are several algorithms to generate TIN from the input data. Input source data can be from points, contours, breaklines such as ridges, valleys, etc. Delaunay triangulation algorithm is a well-known TIN generation algorithm. In this technique, all the nodes are connected to the nearest neighbors to form triangles such that the triangles are as equiangular as possible and the circumcircle of a triangle does not contain another sample point inside it. It is advisable to include sample points beyond the boundary of the study area during TIN generation and then clip out the study area. This helps to avoid elongated and stretched triangles along the boundary.

The most common method of terrain mapping is contouring and it can be generated from a DEM or TIN. Contours connect points of equal elevation and the contour interval is the elevation difference between two adjacent contours. Contours do not intersect one another and do not

stop in the middle of the map. Using the terrain data, vertical profiling of a proposed road or canal alignment can be plotted to calculate the earth work (digging/filling) volume. Hill shading technique simulates the terrain view with the intersection between sunlight and the surface. Three-dimensional view (Perspective view) of the terrain helps to view the terrain in various rotations and navigate through it. Another advantage is the generation of intervisibility maps, which are useful in defense applications, telecommunication, etc. Slope and aspect are the important parameters that are derived from terrain data. Slope gives the maximum rate of change of elevation at a location and aspect gives the direction of the slope. Both these parameters are used in watershed mapping, site-suitability mapping, road/canal alignment, etc.

Network Analysis

A spatial network is defined as a set of geographical locations interconnected by several routes. It is a system of linear features connected at intersections (nodes) and it can be defined as a directed graph. It can be stored as a system of linear features using a topological structure. A network is represented as node-arc incidence matrix or node-node adjacency matrix or forward star representation. Common applications of network analysis are finding the shortest route from a source and destination, locating a closest facility, and solving location-allocation problem.

In the case of road network, the database consists of spatial features such as road links and nodes and attributes, namely, link impedance, turn impedance, one way, flyovers, underpasses, etc. In the shortest path analysis, the system finds the optimal path with the lowest impedance from an origin to destination passing through desired stops. It is very useful to get solution in traveling salesman problem. A well-known algorithm is Dijkstra's algorithm. Network analysis is used to identify the closest facility (e.g., a post office) from a given location. It also helps to allocate the part of the network to a closest facility center in terms of time and distance. Service area mapping is one of the well-known utilities in network analysis. In location-allocation analysis, optimal distribution of resources from warehouses to demand nodes can be mapped minimizing the travel distance. It is a powerful tool in transportation planning and management.

Statistical Analysis

As geospatial science and technology revolves around spatial and attribute data, many statistical measures help in analyzing the data and highlight the measures in visualization. Descriptive statistics uses the data, which are in interval and ratio scales and calculates mean, median, mode, standard

deviation, skewness, and kurtosis. As spatial objects have significant impacts on their neighborhoods, spatial autocorrelation is another important parameter that helps to measure the dependence on nearby values and bring out spatial patterns.

Trend surface analysis helps to understand the spatial trend locally or regionally for various properties such as rainfall, elevation, income distribution, infrastructure availability, etc. The trend surface can be linear or quadratic or third degree surface generated using the input location data.

Spatial interaction occurs due to movement over space and it can be population migration, commodity flows, etc. Gravity models are the most widely used types of spatial interaction models (Lo and Yeung 2002). If two cities have population p_1 and p_2 and they are separated by a distance d , then the spatial interaction can be expressed as the product of population divided by the distance ($p_1 \times p_2/d$). The distance can be geometrical distance or time distance or social distance. With population, exponents can be added in terms of income, etc. To build decision support systems, external statistical models get integrated with geospatial tools to provide solutions to the decision makers.

Visualization of Data Analysis

The results and outcomes of spatial analysis have to be expressed in such a form that the end users can easily understand and get the benefits. Spatial data visualization is an important step and maps are the most effective medium of communication. The map elements are title, body, legend, scale, north arrow, projection name, data sources, etc. Cartography is the subject that gives the methods on preparation of maps.

In vector data visualization, varied symbols can be used for point features, different width of lines for line features (e.g., thin blue line for a tributary and a thick blue line for a river) and varied fill patterns to show area features. The visual variables for a map display are size, shape, texture, fill pattern, hue, saturation, and intensity. Generally, elevation data is shown on 3-D surface and draping a thematic feature over it enhances the visualization. Color maps are preferred over black and white maps. The properties of hue, saturation, and intensity help to improve the color maps presentations. In the case of raster maps as grid is the basic unit, different colors are given to the grids to depict the features.

Maps can be categorized based on the usage. A topographic map is a general purpose map giving information on administrative units, drainage, elevation contours, land use, settlement areas, etc. A thematic map depicts a theme (land use, soils, etc.). A dot map shows quantitatively a property such as population where a dot may indicate one million. Statistical maps use pie and bar diagrams to quantitatively show more than one property (e.g., number of males

and females in a state in a country map). Isarithmic maps show isolines where an isoline connects points of equal value. While preparing the layout, the map body is placed at the center and other map elements have to be placed in such a way that the map looks balanced. A properly designed map can communicate the results well to the end user.

Spatial Decision Support Systems

A spatial decision support system (SDSS) provides a framework for integrating spatial database with geospatial analysis tools, statistical packages, and well-developed economic and environmental models. A SDSS tries to offer modeling, optimization, and simulation features for generating, evaluating, and recommending alternate strategies in decision-making task. The process in SDSS involves iterative, integrative, and participative steps. There cannot be a single SDSS to solve all problems. For each specific application, a SDSS must be designed as per the requirements. To build a SDSS, the initial step is to clearly define the problem, decompose the problem into subunits, and identify suitable models and algorithms to solve the subunits. The system design must have the capability to acquire knowledge from the end user, support multiple representations, and provide better visualization of the results in tables, maps, and through virtual navigation.

Spatial Data Accuracy Assessment

One of the main research issues in geospatial information science is accuracy. It includes several parameters such as original data quality, error, uncertainty, scale, resolution, data input methods, analysis techniques, presentation, interpretation of the results, etc. One cannot make an assumption that the input data are fully perfect. The results must give some indicators on data quality and an estimate of confidence about the results. Generally, the data are collected from different sources. In addition, vast amount of data are downloaded using the internet without knowing the quality at the production level. Even though the input spatial data are inaccurate to some degree, they are represented in high precision digitally in the computers.

The components of data quality are positional accuracy, attribute accuracy, geographical extent of dataset, completeness of data, the data source documentation, classification and sampling methods, boundary definitions, lineage, etc. Positional accuracy is defined as the closeness of location information to the true position on the ground. If a line width is 0.5 mm on a 1:50,000 scale printed map, it is

equivalent to 25 meters on the ground. Knowing the errors on the source document, during geo-registration and digitization process, a root mean square value can estimate the positional accuracy. In most of the cases, attributes are time dependent. Attribute accuracy can be estimated using the time of collection of the source data. The extent of data set must cover the entire study area. Data completeness is controlled by the rules of selection, generalization, and scale. Use of larger scale maps help to improve the quality. Another factor is the source media. A paper map may shrink or swell due to atmospheric conditions, which may introduce distortion during geo-registration.

Spatial data may have classification errors. In raster data, classification is done based on grid and the variations within a grid are not shown. In vector data, the classification of a theme is user defined. In primary data collection, sampling on the ground may be random, systematic, or stratified sampling. Important data may get missed due to the sampling method used. In thematic maps such as soil maps, the boundaries between two categories cannot be clearly defined and there is always fuzziness in the boundary areas. With every data, additional information on the source, method of preparation, symbols used, area of coverage, time of the survey, etc., will help to assess the data quality. Lineage provides the history of the source data. Presently metadata standards are emphasized globally to be adopted along with spatial data sources. The data quality is directly proportional to the data cost. The inherent uncertainties present in the data may result in making flawed decisions. The provision of data quality in proper documentation is very essential for improving the accuracy in the analysis.

In addition to data quality, errors occur during scanning, digitization, cleaning, multilayer registration, error propagation during analysis, improper visualization, and misinterpretation of the outcomes. One of the important and challenging areas in geographical information science is the quantification of error at every step and indicates it in terms of percentage of accuracy in the results.

Applications

Development of geographical information science and the implementation of its outcome through geospatial technology are to solve the real-world problems. It includes simple spatial query to high-end modeling problems. Availability of more and cheaper data and the success of applications for socio-economic benefits have increased the number of users in many folds. Internet technology provides easy to use simple and low cost methods to access, query, and view the spatial data. Major areas of applications cover natural resources

mapping and management, transportation, utilities, health and human services, engineering areas, cartography and map publication, communications, disaster management, education, defense, business, and so on.

Under natural resources sector, GIS is applied in agriculture, hydrology, land use planning, forestry, landscape conservation, archaeology, caves mapping, environmental management, marine and coastal mapping, mining and earth sciences, petroleum, etc. In forestry, geospatial technology helps to monitor forest growth, forest depletion, forest fire, reforestation, harvest scheduling, and so on. In the area of mining and mineral exploration, it helps to integrate data from geology, geophysics, hyperspectral airborne images, field surveys to delineate the mineral zones qualitatively, and estimate the ore content quantitatively. It empowers us to study environmental problems and impact assessment to protect the natural resources.

In transportation, geospatial technology is used for varied purposes like modeling travel demand, planning the road network, monitor the real-time traffic, management of transportation infrastructure, maintaining the roadway assets, etc. Routing and scheduling for on-time delivery and services is another important application. It is a powerful tool in utility management for utilities such as water supply, sewerage, electricity, telephone, etc.

In the government sector, geospatial technology helps in the areas of economic development, elections, security, law enforcement, crime mapping, public safety, disaster mitigation and management, land records and cadastral solutions, urban and regional planning, and sustainable development. It supports all aspects of disaster management, namely, planning, response and recovery, coordination with multiple agencies, and protection of the resources. It plays a key role to establish the principles of sustainable development. In the health sector, it is a vital tool for scientists and public health officials to investigate the cause and spread of diseases around the world. In the business sector, a host of applications are available including selecting the best sites, profiling customers, analyzing market areas, updating and managing assets and location-based services to users. It enables telecommunication professionals to integrate location-based data into analysis and management processes in network planning and operations.

In the area of defense, geospatial technology helps in mapping, base operations and facility management, force protection and security, command and control, intelligence, surveillance and reconnaissance systems, logistics, mission planning, modeling, simulation and training, terrain analysis, visualization, etc.

Research Challenges in Geographical Information Science

Geospatial technology is an outcome of the research in Geographical Information Science by academia and coordinated efforts of government organizations and industries with academia. This technology has witnessed a spectacular growth in the last four decades. As an offshoot from academic research, it has become a core technology for information resources management and decision making in government and businesses. Opportunities are growing in hardware and software development, research areas, and practical implementations. With the introduction of Web, it has entered in the homes of millions and hands of billions.

There are several issues that need our attention. Basically, geographical information is inherently complex in nature. People want to use the technology for wide range of applications and the scope is increasing. In the technological front, there is a rapid advancement. Huge amount of spatial data are getting generated using various technologies. There is a need for well-trained manpower to handle the implementations.

Vast amount of data are available through government sources and commercial suppliers. Public participation generates Volunteered geographical information (VGI). Multi-source data integration is a complex task as the data may be in incompatible formats with varied cartographic specifications such as scale, map projection, accuracy, and symbology. Metadata standards are getting developed globally. Sharing geographical data through formal standards is yet to become reality. Data ownership, copyright, and cost recovery discourage users from using the existing data. Also when the data are updated or modified or augmented, the ownership becomes an issue. Next comes the data security. A balance act is needed between the public's right to know and the individual's right to maintain privacy. The inherent uncertainties in the data may increase the possibility of getting wrong outcomes. Handling geometric incompatibility among multidata sets due to scale, projections, datum, etc., is a challenge. During mosaicing nearby maps, mismatch of features across boundaries may occur. The datasets need updation at regular intervals, which is a tedious and time-consuming task.

In the context of big data, the spatial data has 3Vs, namely, variety, volume, and valuable. New data models and new computational algorithms have to be developed to handle these semi-structures and unstructured data. The big data must be semantically annotated to make it understandable by both humans and machines. The machine learning techniques and process models have to interact with each other. There is a need for parallel/stream/cloud/grid computing engines for real-time analysis. New database structures,

search engines, and visualization techniques have to be developed. Modeling uncertainty and ambiguity in big data is a research challenge.

Research Areas

Study of geographical information both in systems and science perspectives have opened new research opportunities in computer science, computational geometry, spatial statistics, geography, etc. Technologies such as LIDAR, drones, high resolution satellites, and scanners produce volumes of data with high accuracy and speed. Integration of these datasets collected by different technologies in different accuracies and formats is a big challenge. Attempts are being made to develop techniques to extract information from these large set of spatial data using spatial data mining and knowledge discovery.

The focus on GIScience needs to shift from representation and analysis of the form of the Earth's surface to a much stronger concern for the processes that define its dynamics. (Goodchild 2004). Research is needed to develop representation of geographical processes independent of geometry but based on human cognition. It has to be on spatial concepts, categories, processes, and their interactions. Spatial computing algorithms have to be developed with input from Mathematics, Statistics, Computer Science, and Geography. A spatiotemporal process can be very complex to model and the complexity can be simplified by breaking the process into several components (Singh and Venkatachalam 2013). In space-time modeling, several approaches are being developed to model space time data, namely, physical modeling, space-time geostatistical modeling, time series of spatial processes, spatial processing of time series, and hierarchical modeling approach.

In spatial statistics, statistical methods must be developed to compute and analyze the data in spherical coordinates. Algorithms for space time interpolation of large datasets are needed. Use of statistical methods may help to quantify positional uncertainty, fuzzy boundaries, and accuracy of predictions. Present data structures and algorithms have to be modified to speed up computations.

One of the important research challenges is spatial data security. Very little attention has been given to address security concerns such as access control, security, and privacy policies at storage and dissemination level. Issues on research are protection of the ownership of geospatial data at dissemination; task-based and feature-based control at storage level; and secure, efficient, and computationally inexpensive geospatial data outsourcing. One way for data protection is watermarking. The requirements are watermarks that have to be invisible, robust during geometric transformations, cropping, format change, etc. One of the important

characteristics of geospatial vector data is its positional accuracy (Zope et al. 2015). The embedding watermark in vector data should preserve positional accuracy and topological relationships. In raster data, it must be near lossless and maintain the classification. It is better to combine watermarking with cryptography for better protection. During storage, there has to be control-based access with specifications and enforcement of policies. While outsourcing the data, efficient transformations can be followed such that the authorized users can get the results using keys received from the original source.

Open research areas in geographical information science include development of multidimensional GIS, spatiotemporal GIS, modeling of spatiotemporal phenomena, representation of variable resolution data, parallel/distributed/grid/cloud computing in geospatial domain, prediction of moving objects, estimation of uncertainty and modeling of error propagation in analysis, and improved visualization techniques.

Web technology has changed everything and GIS is no exception. WebGIS is the combination of Web and GIS (Fu 2018). WebGIS has grown during the last two decades. WebGIS has unlocked the power of GIS and has reached millions of users. Web technology with read and write has resulted in abundance of user generated content. Web services with cloud help to build new applications. Databases are getting generated with public participation (VGI) and there are several web mapping applications such as Google Maps, Google Earth, Microsoft Bing maps, Yahoo Maps, etc. OGC has developed open standards for geospatial web services. WebGIS is a powerful tool for E-Governance and a huge facilitator of public services. It can provide broad geospatial intelligence to decision makers with its rich source of real-time datasets. It provides a new business model with advertisement-based web mapping, location-based services, etc. It is one of the easiest tools to teach spatial literacy in schools and in Neogeography.

There are several open areas of research in WebGIS. With large amounts of VGI, the research has to focus on quality, integrity, accuracy, and personal privacy. Geotagging can enrich the spatial data and can be used in data mining. Geoparsing can help in disaster management and military intelligence. Geotargeting will be useful in e-commerce and tourism. Sensor web can help in near real-time analysis. Cloud-based GIS can provide quicker development time, mobility, reduced cost, and dynamically scalable databases. Semantic web is trying to add meaning to every information on the web so that the web data can be understood and processed by machines.

Conclusions

This entry discusses briefly the various components of Geographical information science and the open areas of research.

Geospatial technology and Computers can synthesize data and perform analysis and modeling. But, people make decisions. Users are from diverse technical background. There is a huge shortage of skilled specialists who can design the systems and develop applications. Sound GIScience education is needed to provide solid formation of the theoretical aspects including mathematics, statistics, computer science, geography, etc. In the academic front, GISc has widened its scope and research getting evolved on new concepts, model, geographical computing, and application. Challenges and the solutions in Geographical Information Science will enhance the capabilities of geospatial technology to provide massive benefit to the society.

Definition

Geographically weighted regression (GWR) (Brunsdon et al. 1996; Fotheringham et al. 2015, 2003) is a technique that extends the traditional regression framework by allowing different linear relationships to exist at various locations in space. It is a local method for analyzing *spatial heterogeneities* of processes and is widely applied in geography and other related disciplines. The underlying idea of GWR is that each observed point in the study areas borrows a certain number of its nearest neighbor points to build pointwise regression models.

Introduction

The general global linear regression model commonly assumes that the same relationships hold throughout the entire study area (i.e., constant across space). It can build the relationship between a dependent variable and one or more independent variables, whose general form is as follows:

$$y_i = \beta_0 + \sum_{k=1}^n \beta_k x_{ik} + \varepsilon_i \quad \text{for } i = 1, 2, \dots, n \quad (1)$$

In Eq. 1, x_{ik} is the k th independent variable measured at a location i , and y_i is the corresponding dependent variable. ε_i denotes the random error term, which is assumed to be independent and drawn identically from the normal distribution $N(0, \sigma^2)$, i.e., β_0, β_k are coefficients which are usually to be estimated by minimizing the value of residual sum of squares (RSS), i.e., $\sum_{i=1}^n (y_i - \hat{y}_i)^2$ ($\hat{y}_i$ denotes the predicted value for the i th observed location). Such a global model is usually fitted by the method of **ordinary least squares (OLS)**. The coefficients can be estimated by OLS estimator take the matrix form:

$$\hat{\beta} = (X^T X)^{-1} X^T y \quad (2)$$

In Eq. 2, $\hat{\beta}$ denotes the vector of estimated coefficients, X is the matrix which contains the independent variables and a

constant column of 1. X^T is the transpose of X , and $(X^T X)^{-1}$ is the inverse of the **variance-covariance matrix**.

In the geospatial context, it is not always the case with some assumptions underlying the general global linear regression model. As Tobler's first law of geography goes "Everything is related to everything else, but near things are more related than distant things" (Tobler 1970), both the errors and the variables in the model might exhibit spatial correlations. Observed spatial variables will usually have spatial effects, which are caused by their spatial correlation structures. Two broad classes of spatial effects may be distinguished, referred to as spatial dependence and **spatial heterogeneity** (Anselin 1988). Spatial error or spatial lag models are appropriate when there appears to be spatial dependence structures in the residual term or the variables. It is assumed that relationships being modelled are the same everywhere in the study area in general global linear regression. However, there is often appropriate that the spatial processes might vary across space, which is referred to as spatial heterogeneity (Charlton et al. 2009).

Model Formulation

Geographically weighted regression (GWR) relaxes the assumptions of constant coefficients across space, that is, allows the relationships between the dependent variable and one or more independent variables to vary with their spatial locations. It is a useful tool for modelling spatially heterogeneous processes whose general formulation can be defined as:

$$y_i = \beta_0(u_i, v_i) + \sum_{k=1}^n \beta_k(u_i, v_i) x_{ik} + \varepsilon_i \quad (3)$$

for $i = 1, 2, \dots, n$

In Eq. 3, the **coefficients** β_0, β_k vary according to their location i in the study area, which are spatially varying coefficients (SVC) that quantifies variations in the processes and the relationships between spatial independent and dependent variables. These coefficients may be estimated anywhere given a dependent variable and a set of independent variables observed at places whose locations are known. Its estimator, which is based on the **weighted least squares (WLS)**, conditioned on the coordinates (u_i, v_i) of location i , which takes the form:

$$\hat{\beta}_k(u_i, v_i) = (X^T W(u_i, v_i) X)^{-1} X^T W(u_i, v_i) y \quad (4)$$

In Eq. 4, $W(u_i, v_i)$ denotes the weighted matrix whose off-diagonal elements are 0. The weights in the matrix are generally generated by a distance decay function that is known as a kernel function.

$$w(i) = \begin{bmatrix} w_1(u_i, v_i) & 0 & \cdot & \cdot & 0 \\ 0 & w_2(u_i, v_i) & \cdot & \cdot & 0 \\ \cdot & \cdot & w_3(u_i, v_i) & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & \cdot & w_n(u_i, v_i) \end{bmatrix} \quad (5)$$

Gaussian and **Bi-square** kernel are two widely used kernel functions in the GWR-based model, which are given in Eqs. 6 and 7, respectively.

$$\text{Gaussian : } w_{ijS} = \exp \left[-\frac{1}{2} \left(\frac{d_{sij}}{b_S} \right)^2 \right] \quad (6)$$

$$\text{Bi-square : } w_{ijS} = \begin{cases} \left[1 - \left(\frac{d_{sij}}{b_S} \right)^2 \right]^2, & \text{if } d_{sij} < b_S \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

In Eqs. 6 and 7, d_{sij} is the spatial (Euclidean) distance between the regression point i and an observed data point j . b_S is a quantity known as the spatial bandwidth, which is in the same units as the coordinates used in the dataset. There two different weighting strategies of using the bandwidth for calculating the weighted matrix in GWR: a fixed spatial bandwidth strategy and an adaptive spatial bandwidth strategy. The former uses a specified spatial bandwidth for calculating weights, which is usually based on sufficient knowledge of the problem. In contrast, the latter uses a searching strategy to obtain the optimized spatial bandwidth through model diagnostic values.

Model Calibration

The GWR, which combine the WLS estimator, kernel and bandwidth, is regarded as a local model for exploring spatial non-stationarity. Several diagnostic values are used for the measurement of goodness of fit, such as the corrected **Akaike Information Criterion (AICc)** (Hurvich et al. 1998) or **cross-validation (CV)** score (Cleveland 1979). Their calculating formulations are given in Eqs. 8 and 9, respectively.

$$AIC_c = 2n \ln(\hat{\sigma}) + n \ln(2\pi) + n \left\{ \frac{n + \text{tr}(S)}{n - 2 - \text{tr}(S)} \right\} \quad (8)$$

In Eq. 8, n is the sample size, $\hat{\sigma}$ is the estimated standard deviation of the error term, and $\text{tr}(S)$ denotes the trace (the sum of the values in the leading diagonal) of the hat matrix S (Hoaglin and Welsch 1978). The hat matrix S is an interesting matrix in regression modelling. We will obtain the vector of predicted dependent variable $\hat{y}$ when the observed values of y are pre-multiplied by S , i.e., $\hat{y} = Sy$. In a GWR model, the effective number of parameters, which depends on the

bandwidth and the number of independent variables, can be obtained by the expression $2tr(S) - tr(S^T S)$.

$$CV = \sum_{i=1}^n [y_i - \hat{y}_{\neq i}(b)]^2 \quad (9)$$

In Eq. 9, $\hat{y}_{\neq i}(b)$ is the fitted value of y_i with the observed data for location i omitted from the calibration procedure. This approach calibrate model only on samples near to location i and not at i itself, countering the “wrap-around” effect.

In the calibration of the GWR model, we usually use a searching strategy (e.g., Golden-section search) to obtain the optimized spatial bandwidth and then calculate the weighted matrix. Thus, the coefficients $\hat{\beta}_k$ can be estimated by Eq. 4.

Model Output

GWR model can output a series of location-specific estimated coefficient values that can help users analyze the spatial non-stationarity. Besides, the model can also provide the estimated local standard errors, calculated local goodness of fit, local t statistics, local p -values, and so on. Out-of-sample points can also be predicted by the GWR model, given the values of the independent variable at the corresponding position. GWR model can output a series of location-specific estimated coefficient values that can help users analyze the spatial non-stationarity. Besides, the model can also provide the estimated local standard errors, calculate local goodness of fit, perform inferences based on local t statistics, evaluate the significance of spatial changes, and so on. The GWR model can also be used to predict out-of-sample points, given the values of the independent variable at the corresponding position.

Case Study

We selected hourly weather data and the elevation as independent variables to analysis their relationships with the value of **air quality index** (AQI) of 16 monitoring stations in Beijing, China. We build the **GWR** model as the formation below:

$$\begin{aligned} AQI_i = & \beta_0(u_i, v_i) + \beta_1(u_i, v_i)TEM_i + \beta_2(u_i, v_i)HPA_i \\ & + \beta_3(u_i, v_i)WET_i + \beta_4(u_i, v_i)WS_i + \beta_5(u_i, v_i)WD_i \\ & + \beta_6(u_i, v_i)ELE_i + \varepsilon_i \end{aligned} \quad (10)$$

where AQI is the dependent variable, TEM denotes the air temperature ($^{\circ}\text{C}$). HPA is the air pressure (hPa), WET is the relative humidity (%). WS is the wind speed (m/s), and the WD is degrees of wind direction (start from counterclockwise east). ELE is the elevation.

The hourly AQI data in April 30, 2016, source from the website <http://beijingair.sinaapp.com>, and the corresponding weather data source from the Beijing Municipal Data Resource Network (<http://106.38.57.109/>). Table 1 shows some fitting results of fitted GWR model. The residual sum of squares (RSS) is only 764.78, which is only 6.3% of the OLS. And both the $AICc$ and R-Squared (R^2) are significantly better than the OLS model. The results of OLS shows that it performs very poorly in the study area because it is trying to fit a global model to a nonstationary process. The means of estimated coefficient values by GWR are also different from the OLS estimated ones.

In this case, we use the inverse distance weighted (IDW) interpolation method to generate the surface of each independent variable. We then use the fitted GWR model to predict the spatial surface of AQI (as shown in Fig. 1). Through this method, we can obtain the estimated spatial surface of the dependent variable (as well as the predicted coefficient surfaces), which is useful for analyzing the heterogeneity of the spatial process.

Extensions to GWR

The GWR model is implemented in many open-source packages and software, such as R package “spgwr,” python package “MGWR,” and GWR 4.0. Therefore, GWR is explicitly applied in many spatial-related fields, including mineral potential modelling (Wang et al. 2015), health risks (Li et al. 2017), climate variation (Hu and Xu 2019), and so on. However, this model is not appropriate for all types of spatial data. There are many variants of the GWR model to deal with various spatial heterogeneity issues. For examples, if the dependent variable is count data, a **Poisson** extension of GWR model should be used for analyzing. If the dependent variable is binary, a **logistic** extended GWR model is needed (Atkinson et al. 2003). And there are also temporal extensions of GWR models, such as the **geographical and temporal weighted regression (GTWR)** (Fotheringham et al. 2015) and **spatiotemporal weighted regression (STWR)** (Que et al. 2020, 2021).

Geographically Weighted Regression, Table 1 Modelling results of case study

Models	RSS	$AICc$	R^2	$Est \beta_0$	$Est \beta_1$	$Est \beta_2$	$Est \beta_3$	$Est \beta_4$	$Est \beta_5$	$Est \beta_6$
OLS	12133.09	165.50	0.31	18381.63	23.791	-18.80	3.83	-15.82	-0.05	-1.94
GWR	764.78	137.83	0.96	7497.01	11.81	-7.59	1.63	-16.63	-0.07	-0.25

Note: $Est \beta_0$, $Est \beta_1$, $Est \beta_2$, $Est \beta_3$, $Est \beta_4$, $Est \beta_5$, $Est \beta_6$ of GWR are the mean of the estimated coefficient of const, TEM , HPA , WET , WS , WD , and ELE , respectively

Geographically Weighted Regression, Fig. 1 Predicted AQI surface of GWR model

Conclusions

GWR is a widely used statistical model, which can be applied to explore the spatial heterogeneities. It can build pointwise regression models by borrowing points from spatial neighbors. This model can generate the local regression coefficients, which can help reveal the strength of the spatial effect of each independent variable to the dependent variable at some places.

Groundwater in a surface mining operation can create a number of water-related problems affecting the mines' design and

economic viability. Groundwater inflow from the surrounding strata toward the mining excavation requires installing large-scale dewatering facilities to lower the water table and create an extensive and prolonged cone of depression (Doulati Ardejani et al. 2003a). A hydrogeological investigation of the mine site is necessary to design an appropriate dewatering technique. The hydrogeological characterization program is required to be implemented at an early stage of the mine evaluation process, specifically to help quantify the probable pore pressure conditions in the pit slopes (Read et al. 2013). The collection of hydrogeological data such as hydraulic conductivity, storage coefficient, and pre-mining groundwater flow regime are the main factors in designing an appropriate dewatering technique. Sequential investigation levels for a hydrogeological project include an inventory of existing data, remote sensing interpretation, hydrogeological fieldwork, geophysical surveying, and exploratory drilling. The method presented in this chapter provides an appropriate framework to investigate hydrogeological conditions around an open-pit mine to control water-related problems.

Introduction

Hydrogeological characterization of a specific area can be achieved by estimating a set of aquifer parameters, such as aquifer thickness and extent, hydraulic conductivity, hydro-lithological units, and tectonic features (Keller and Pinter 1996). To accurately design a dewatering system in an open-pit mine, it is necessary to determine the exact amount of water that enters the pit. For this purpose, a hydrogeological investigation has to be conducted to properly identify the aquifer surrounding the mine site. The obligations of the mine hydrogeology group usually include (Doubek et al. 2013):

- Detailed characterization of the groundwater system
- Installing a monitoring or piezometer network in order to support continued hydrogeological characterization and to monitor the performance of dewatering and pit slope depressurization measures
- Installing horizontal drains
- Performing aquifer tests
- Locating suitable dewatering well sites by drilling and testing pilot holes
- Designing and supervising the installation of production dewatering wells
- Sizing pumping equipment
- Collecting data and maintaining a robust database of water levels, pumped volumes, flow rates, and water chemistry
- Reporting dewatering progress to mine management

The hydrogeological fieldwork must include the groundwater system's adequate characterization and hydraulic properties within the mine area and the surrounding region.

Open-pit mining operations below the groundwater table can result in extreme inflow to the mine workings and water-related severe problems affecting the mining operations' design and economic viability. In other words, unexpected inflow in large quantities can cause (Singh and Atkins 1984; Morton and van Mekerck 1993):

- Impeding production
- Delaying the project
- Reducing the stability of the strata and resulting in the pit slope stability problem
- Causing many environmental problems
- Forming a pit lake and causing a long-term water quality problem
- Losing access to all or part of the mine working area
- Increasing the use of explosives
- Rising the explosive failures resulting from wet blast holes
- Needing the use of special explosives
- Resulting in inefficient loading and hauling
- Creating unsafe working conditions

This inflow from the surrounding layers toward the excavation requires dewatering facilities to keep the mine workings dry, create an extensive and prolonged cone of depression, and increase the pit wall slope stability. Mine abandonment, groundwater rebound due to cessation of dewatering and associated pollution issues, is considered a severe mining problem throughout the world (Henton 1981). If the effects and magnitude of a water-related problem can be recognized in advance of mining, appropriate water management strategies to minimize the socioeconomic and environmental impact of mine dewatering often can be efficiently incorporated into the mine plan. To design an effective drainage scheme for a surface mine, the prediction of water inflow into a mining excavation is a crucial component of the operation's feasibility stage (Singh and Reed 1987).

Dewatering of open-pit mines during mining operations can place considerable hydrological stress on the regional groundwater flow system by creating an extensive and prolonged cone of depression, regional groundwater table lowering, overlapping cones of depression, land subsidence, and water quality deterioration, which can endanger mine productivity and human life (Keqiang et al. 2006). When mining is completed, and the dewatering operations have ceased, the water table or hydraulic head (in the confined aquifer) rebounds. The rising groundwater forms a pit lake. The groundwater in contact with the pit wall strata containing sulfide materials may be contaminated with pyrite-oxidation products. Hence, prediction of post-mining water table elevation within the pit is essential. The adverse effects can be countered with an appropriate addition of alkalinity to the contaminated water and special rehandling techniques. Many analytical and numerical models have been applied in the past

to estimate water inflow into surface mining excavations (Singh and Atkins 1984; Singh and Reed 1987; Hanna et al. 1994; Doulati Ardejani et al. 2003a; Bahrami et al. 2014). Comprehensive studies including analytical and numerical modeling and field observations into groundwater recovery after cessation of dewatering operation in mining excavations have been reported by many researchers (Reed and Singh 1986; Doulati Ardejani et al. 2003b).

In this chapter, the main steps for predicting groundwater inflow into an open-pit mine and post-mining groundwater rebound using numerical models, proposed dewatering system, and the associated costs of each stage study have been presented.

Open-Pit Mine Dewatering

A mine dewatering program's main aim is to lower the water table below the pit floor and remove residual groundwater seepage and surface water runoff inside the pit. According to Norton (1983), the dewatering process has the following effects:

- Creates a cone of depression in the vicinity of the mining excavation
- Reduces the hydraulic gradient in the aquifers
- Increases the slope stability
- Controls mine excavation flooding

A hydrogeological investigation of the mine site is necessary to design an appropriate dewatering technique. The collection of hydrogeological data are the main factors in designing appropriate dewatering techniques. Depending on the pit's geology and hydrogeological condition, several groundwater control methods, including peripheral (active) and in-pit dewatering techniques, are proposed to conduct a successful mine dewatering operation. Active dewatering techniques (Norton 1983) are often used in surface mine sites where a large amount of groundwater inflow into the excavation is expected.

Dewatering Techniques

Passive Dewatering

As soon as the pit is progressed to below the water table, small quantities of natural drainage will usually occur on the pit wall, in response to seepage and potentially in response to the rock mass's mining-induced relaxation. This drainage results in a reduction in the pore pressures in the pit slopes. In passive dewatering, a sump is often excavated at the pit bottom, and the groundwater is allowed to enter the sump, where it is eventually pumped out. This method is recommended for

Geohydrology, Fig. 1 Schematic view of passive (left) and active (right) dewatering techniques (Read et al. 2013)

open pits where a small amount of groundwater is expected and for controlling surface runoff and direct precipitation (Norton 1983).

Active (Advance) Dewatering

In many open-pit mines, the pore pressure dissipation rate obtained by passive dewatering is too low to maintain the water table drawdown in advance of the mine excavation level or achieve the pit walls' target depressurization levels. In these cases, an active dewatering program can be implemented to reduce pore pressure in the wall and keep the pit faces relatively dry. In this method, electrical submersible pumps must be installed in vertical boreholes drilled within the geological layers inside and around the perimeter of the pit. However, horizontal drains can be considered an effective way to depressurize and drain aquifer in the west slope and similar situations that may occur during the next phases of mine development (Norton 1983). Figure 1 shows a schematic representation of dewatering techniques.

Groundwater Flow Model

Successful dewatering necessitates a hydrogeological assessment of the mine site. This may be achieved through numerical modeling. Models are extensively used to quantify the dewatering rates, design dewatering programs, and examine such programs' efficiency. To design an effective dewatering program for an open-pit mine, predicting the water inflow into the pit using an appropriate groundwater flow model is a significant task. A groundwater model is a computational technique representing an approximation of a groundwater system (Anderson and Woessner 1992). There are different types of groundwater models. The mathematical model is the

most common model used to simulate groundwater flow problems. A mathematical model attempts to simulate the flow system's actual behavior through the solution of mathematical equations (Schwartz et al. 1990). Groundwater flow models can simulate the hydraulic head distribution and groundwater flow rates within and across the systems' boundaries under consideration (Ünsal 2013). The use of numerical modeling codes such as SEEP/W (Geo-slope International 2014), MODFLOW (McDonald and Harbaugh 1988), and FEFLOW (Diersch 1992) enables us to address complicated groundwater problems associated with the mining operation.

Study Schedule

A comprehensive hydrogeological study is carried out in an open-pit mine site as the basis for the development of a proper dewatering plan to overcome water inflow. Table 1 summarizes the activities which are conducted concerning the mine hydrogeological investigation.

Conclusions

A variety of groundwater control techniques can be used to conduct a successful mine dewatering, depending on the geology, hydrogeological condition, and mine type. This allows pit dewatering and lowering the groundwater level adjacent to pit walls. According to the hydrogeological study result, the water inflow is a critical issue in an open-pit mine area, affecting the pit slope stability and causing a wet working environment for the mining operation. The passive dewatering from the lowest zone of a pit floor level is just a temporary solution.

Geohydrology, Table 1 A step-by-step investigative procedure of open-pit mine hydrogeology

No.	Task
1	Literature survey Literature survey of the mining operations and associated water inflow problems, inflow sources into open-pit mines, inflow types, and flow regime in aquifers Open-pit mine dewatering and pit slope depressurization Post-mining groundwater rebound and pit lake formation A review of numerical methods, governing flow equation, groundwater flow models Preliminary interpretation of the hydrological and rainfall data
2	Data collection/preliminary design Remote sensing, satellite images, and airborne magnetic data interpretation Hydrological data (rainfall, evaporation, temperature) Surface water (runoff, stream flow records) Hydrogeological features (springs) Data extraction from available maps (geology, ore geology, hydrogeology, topography, and structural features) Preparing a checklist for fieldwork, sampling, and water quality monitoring program Designing the horizontal drains for those segments of the pit wall where there is a risk of instability Supplementary interpretation and modeling the geophysical (IP/RS, magnetic) data Large- and local-scale watershed and sub-watershed analyses using digital elevation model and GIS tool Determining the general water flow direction Designing the new geophysical profiles and points
3	Field operation and surveying the study area Site visiting and primary investigation (double-check of designed geophysical profiles and points) Determining the locations and drilling open observation holes and measuring groundwater levels Groundwater level measurements in springs and the existing exploration boreholes Conducting a geophysical survey – resistivity and magnetic surveys Site detailed investigation for designing a conceptual hydrogeological model (investigating the hydrological, hydrogeological, environmental, and ecological characteristics of the study area) In situ measurements for water quality parameters (pH, temperature, EC, DO, ORP, and salinity) Hydro-geochemical sampling from available boreholes, open observation holes, springs, and seeps Soil sampling for permeability test around the pit and watershed surface soils Double-checking the geological features, lithology, faults, and discontinuities according to the structural map Inspecting the lithological logging during the drilling of exploration well, inspecting the horizontal drains and open observation holes Preliminary determination of groundwater inflow to the pit and inflow type Preliminary determining the rate of pit lake formation Determining and categorizing different seeps around the pit wall Performing a tracer test around the pit
4	Office works and data interpretation Geo-electrical data reduction, processing, preparing the resistivity pseudo-sections and interpretation Modeling the resistivity profiling measurements and producing 2D inverted resistivity sections Modeling the vertical electric sounding (VES) measurements and producing an inverted resistivity model Magnetic data reduction, processing, and enhancement Producing magnetic maps (total intensity, residual field, RTP, analytical signal, vertical derivatives, and upward continuation) and interpretation Producing a modified structural map of the mine area based on the magnetic data surface structural features Determining the hydraulic conductivity of pit wall rocks based on tracer test and hand auger experiment Generating a groundwater table level map from all available groundwater level data and determining groundwater flow direction Generating a groundwater table depth (depth to groundwater level) map Generating bedrock elevation and bedrock depth (depth to bedrock) maps Producing supergene zone map (related to porphyry copper mines) Preparing various cross sections of the aquifer representing geological units, pit layout, groundwater table, and bedrock level
4	Piezometric network and location design Monitoring the piezometers, continuous groundwater measurements, and data evaluation Time-based changes in groundwater levels within the mine site Compiling the hydrological data and deriving a hydrological model of mine catchment
5	Hydrogeochemical data analysis and interpretation (to support hydrogeological study and provide a preliminary estimate of potential environmental concerns) Major, trace, and rare earth element analysis Graphical representation of hydrogeochemical results and preparing water chemistry diagrams Plotting water chemistry maps Statistical analysis of water quality data Speciation and solubility modeling of the hydrogeochemical data Water quality assessment and evaluating potential health effects

No.	Task
6	Description for operating a drilling program Preparing a job description for drilling operation and pumping out test Installation of piezometers Drilling the testing wells
7	Developing a conceptual model Development of a conceptual model based on geological, topographic, structural, geophysical, hydrogeochemical, hydrological, hydrogeological, drilling and mine geometry, and development phases
8	Developing a mathematical model Inspecting the drilling operation, sampling, data collection, and geological logging Inspecting the pumping out test Investigating the aquifer system, boundaries, and zones containing water and determining the hydrodynamic coefficients Developing a groundwater inflow model during mine advancement Determining the height of the seepage face in excavation highwall as a significant parameter of the slope stability Developing a groundwater rebound model Developing a model for hydrogeological regime and hydrodynamic system of a surface mine area
9	Proposing a dewatering system Proposing a dewatering and drainage scheme for a mine area Preparing a job description for dewatering wells Drilling the dewatering wells and inspection Conducting dewatering operation

Apart from lowering the water table near the pit, pumping out operation causes insignificant change to groundwater levels in the surrounding aquifer. Advance dewatering must be carried out to overcome the water inflow issue to the pit. This dewatering technique will be an essential and permanent solution for the future mining operation. A general active dewatering program's primary focus is to lower the water table below the pit floor and remove residual groundwater seepage and surface water runoff inside the pit. It will also positively affect pit slope stability and control the water accumulation on the bench floors in the mine working faces. Runoff must also be controlled to allow effective mining operation. Runoff from the surrounding areas must be diverted away from the pit using collector drains and diversion bunds. Within the mine, surface water from direct precipitation and runoff must be controlled by the drains and sumps to pump water away from working areas. The water pumped out of the dewatering wells or the accumulated water in the water-collecting sumps must be disposed of using pumps and a proper pipeline system. Polyethylene pipes can be used for water transfer. The water collected from the pit should be transferred to a pond outside the pit. Centrifugal pumps are suitable for water removal. Either submersible pumps or pedestal pumps can be used for this purpose. Submersible pumps are put underwater, while pedestal pumps are positioned with the pump motor out of the water. Disposal of the pumped water can create problems, because the discharge water may have a high sediment load, elevated concentrations of iron, sulfate and toxic elements, and low pH which can cause environmental problems at the disposal point, requiring sediment removal (e.g., by passing through a sediment lagoon) and special water treatment techniques. It is

recommended to use a geomembrane liner with appropriate diameters in the external pond to prevent water infiltration into the ground. However, no need to install geomembrane liner for in-pit sumps. It is recommended to add alkaline materials such as limestone, lime, sodium carbonate, or sodium hydroxide to the in-pit sumps to neutralize the acidity and precipitate the trace elements. This in turn increases the quality of the water. Dewatering and mine water management are essential aspects of many surface mine operations. A planned and integrated approach toward water management, incorporating the overall mine development strategy, operational requirements, and environmental considerations, can be developed. Effective dewatering and mine water management strategies bring cost-saving benefits through managing risks and minimizing uncertainties.

It is necessary to develop innovative, cost-effective, and environmentally acceptable technologies, which will be applied on a field scale to prevent acidic drainage generation from hazardous mining waste dumps and neutralize acidic drainages. Treatment of the effluents will be attempted to prevent the transportation of the toxic elements and minimize their adverse effects on the surface- and groundwater systems and soil. Besides, the development of an integrated environmental management scheme, based on the result of a risk assessment analysis, will produce a novel methodology for the proper disposal of the hazardous wastes associated with the future mining development and the application of preventative and remedial technologies for the protection of soil and water quality.

Definition

Geoinformatics is the general term used to describe the process of information entry and retrieval to transform geoscience data and information into knowledge. First introduced in the early 1990s (Merriam 2004), geoinformatics implies the use of computing systems and comprises activities such as “data collection, digitization, management, and transmission of digital data” (Merriam 2004; Allaby 2013).

Introduction

The seeds of geoinformatics lie within the field of quantitative geoscience with an excellent historical review in Merriam and Merriam and Harworth (Merriam 2004; Merriam and Harworth 2004). In its early history, the geosciences were rooted in qualitative methods, focused on non-numeric, descriptive data. The early emphasis on qualitative analysis stems in part from the integral relationship between the geoscientist and fieldwork, observing and describing the various features on the Earth’s surface. This descriptive information is responsible for key theoretical underpinnings including the “Principle of Original Horizontality,” published in 1669 by Nicholas Steno (Allaby 2013), and the *Strata Identified by Organized Fossils*, published first by French zoologist Georges Cuvier in 1812, and expanded by William “Strata” Smith in 1815 (Gohau 1990). Both of these principles were based on qualitative analysis and serve as the foundation of modern stratigraphy.

Quantitative Geosciences: Evolving Computational Systems

The emergence of quantitative geoscience had a significant impact on the early evolution of the discipline, what Merriam (Merriam 2004) refers to as the “origins” and “formative” stages. Prior to the nineteenth century, graphs and charts may have been common, but statistical analyses using large amounts of non-numeric data were problematic. This was due in part to the labor necessary to gather and convert descriptive information into numbers for statistical

computations. The emergence of modern statistics did not occur until the end of the nineteenth century with Karl Pearson, credited with initiating the discipline of mathematical statistics (Cubitt and Henley 1978). While the use of statistics was uncommon, there were significant contributions made. Sir Charles Lyell (1797–1875), whose work contributed to the basis of modern geology, was one of the first to use statistics to establish the order in facies sequences. This was influenced by an impressive interdisciplinary group of colleagues including Charles Darwin, Charles Babbage, Michael Faraday, and other key players in the industrial revolution and the birth of modern science (Merriam 2004).

By the late nineteenth century through the mid-twentieth century, the *exploration* and *development* stages (Merriam 2004), early computer systems were introduced, and the use of quantitative analysis became more common. However, most geoscientists lacked access and/or the technical support required to use these computer systems. Further, they lacked sophisticated methods for data handling and management (e.g., converting the non-numeric data into digital form) (Agterberg 1974). A small group of geoscientists recognized the importance of computers, mathematics, and statistics. Among these players were John C. Griffiths (petrography and statistics), W.C. Krumbein (size-frequency distributions, computer-based stratigraphic facies analysis), L.L. Sloss (statistics and sequence stratigraphy), and Georges Matheron (geostatistics) (Merriam 2004). Joint contributions from other disciplines were also highly influential, an excellent example being Andrey Nikolaevich Kolmogorov. His classic work on “The solution of a probability problem related to the question of the formation of strata” influenced Matheron, Krumbein, and others and arguably planted the seeds of what is today referred to as “mathematical geology” (Shiryaev 1989).

Quantitative Geosciences: Early Computer Engagement

Merriam’s *automated stage* covers the period between 1958 and 1982 with the emergence of personal and desktop computers and the exponential growth in mathematical and statistical applications (Merriam 2004). Figure 1 represents a timeline of representative topics from Earth geoscience history through the present. The topics encompass papers, concepts, events, and technologies covering three geoscience disciplines: geostatistics, classical statistics and data analysis, and engineering. The colored clusters loosely represent topics of similarity and generally show a progression from early theory to commercialization.

The world moved from “mainframe” computers to early supercomputers like the Cray-1 in 1976 and the Cray X-MP in 1982. The Cray X-MP was able to perform 0.8 GFLOPS (Giga Floating Point Operations Per Second) at a cost of

\$15,000,000, which enabled new categories of scientific problems to be addressed (Cray 2020). As of this writing, an AMD Ryzen 3600 CPU and NVIDIA RTX 3080 GPU can produce 30254 GFLOPS at a cost of \$0.04/GFLOP, and a Samsung Galaxy S20 achieves 1,267 GFLOPS for a total cost of \$1000 (FLOPS 2020). At the same time floortop, desktop, and “luggable” computers (Wang 2200-VP, IBM 5100, Osborn 1, Kaypro II, HP9807A) became available (Rhode Island Computer Museum 2020; IBM 2003; History of Computing 2020; National Museum of American History 2020; Hewlett Packard Computer Museum 2020). With the introduction of Silicon Graphics’ high-performance IRIS 1000 and 1400 in 1983 and 1985, respectively, and Windows 1.0 being launched in 1985 and broadly adopted in 1992 as Windows 3.1, a new generation of computational and graphical power emerged (Silicon Graphics – Wikipedia 2020; Earle, et al.; Microsoft Windows 2020). Some universities and large oil companies seized the opportunity to use these new tools and advanced quantitative applications.

This explosion in computational power and its greater accessibility enabled the development of statistical software which paralleled the computer evolution-revolution. A number of large mainframe-based statistical software programs were introduced including the Statistical Package for Social Scientists (SPSS) in 1968, Statistical Analysis System (SAS) in 1976 Biomedical Data Package (BMDP), and the S language for data analysis that was developed in 1976 by John Chambers of Bell Labs in close relationship to the Unix operating system concurrently developed by Dennis Ritchie (S was the precursor to today’s R statistical programming language) (Nie 2020; Aster 2016; Frane 1976; Becker 1994). These packages were in general use in a variety of scientific disciplines including the growing quantitative geoscience community. Some early software development within the geoscience disciplines made a significant impact on Earth sciences. Many of these impacts are identified on the timeline shown in Fig. 1. Of particular note is Surface II, written in Fortran by Robert Sampson of the Kansas Geological Survey (Sampson 1975). This mainframe-based program was perhaps the first integrated geoscience graphics software package that incorporated not only traditional automated contouring and statistical map analysis but also geostatistical kriging and drift analysis (Olea 1975) which had been formalized only 10 years earlier by George Matheron (1965).

As computers have become more computational and graphically more capable, a tension develops between graphics for visualization of data and the main method for user interaction. Donald Knuth points out that the ideal approach is that code should be interwoven with its explanation, and the results of the data analysis should compile to be the final report. This is a useful definition of reproducible science, a challenge to this day. Progress is being made using code-based data science tooling (e.g., RStudio integrated

Geoinformatics Fig. 1 Timeline includes papers, concepts, events, and technologies intended to represent key developments. The chart follows Merriam's quantitative development stages and Ma's suggested current *intelligent stage* (Ma 2019). The color coding is a product of simple clustering by general topic. Events prior to 1950 are lumped together and meant only to remind us of some fundamentals upon which geoscience is based

Geoinformatics, Fig. 2 The *development stage*, *automated stage*, and *integration stage* converge on the Enterprise Geomodeling Software solutions. The path forward in the *intelligent stage* shows movement

into cloud-based high-performance solutions and to the dismantling of enterprise software to microservices across CPUs, GPUs, and TPUs

development environment (IDE) for R coding) (Peng 2011; Broman et al. 2017; Bajuk and Howe 2020).

A successful software package originating from geosciences is Environmental Systems Research Institute's (ESRI) Arc/Info released initially in 1982. Arc/Info was an early geographic information system (GIS), built on the legacy of earlier products (GIS Geography 2020). Today, Arc/Info is a full-featured, menu-driven, enterprise software solution (Fig. 2) and is part of the current ArcGIS Desktop product line. Currently, ESRI is the largest GIS software company. Code-based data science approaches have also been rapidly advancing in geospatial analysis as discussed, for example, in Lovelace's book *Geocomputation in R* (Lovelace et al. 2019).

There is a need for a descriptive term for computational systems and knowledge generation from geoscience information. The vast amount of qualitative data, prior to the current digital age (what Ma calls the *intelligent stage*, Figs. 1 and 2), the influence of early mathematicians and statisticians, and the compelling draw to computer systems by early adopters, would lead today's geoscientists to invent the term "geoinformatics," if it had not been suggested already (Ma 2019). In *Stratigraphy and Sedimentation*, Krumbein and Sloss all but canonized the definition. They stated, "Automatic data processing [in computers] provides the essential means for coping with such large masses of data by providing a mechanism by which data-searching, arranging and analysis can be performed with a minimum of hand labor" (Krumbein and Sloss 1963).

Quantitative Geosciences: The Twenty-First Century

The foundation of modern informatics systems is its integration with information. Prior to the computer revolution, the fundamental informatics system resembled a filing cabinet. The process of composing and adding information (data entry) is considered part of the informatics process. Today, data entry and retrieval has become more sophisticated. Databases can be federated and connected to meaningful analytical processes like data mining, forecasting, imputation, and other multidirectional information feeds, all of which serve to expand and improve data accessibility and richness. The extent of geoinformatic activities is dependent on the infrastructure surrounding the information. Sophisticated federated databases can be designed to find and support multiple data sources and formats, but their effectiveness depends on the volume of accessible rich information and human-computer interfaces or automated machine decisions. Ma suggests extending Merriam's quantitative development stages to include an *intelligent stage* (Ma 2019). He postulates that we have entered a period of information science and computational intelligence, a move that can drive real-time data integration, automated analytics using code-based data science, and deep learning and artificial intelligence.

Modern database technology, machine readable data, and changes in computational systems are examples of geoinformatic computational intelligence and changing the way we work to solve technical challenges.

Databases. Database systems can be broken down into **relational** and **non-relational databases**. Relational databases store data in a variety of tables related to each other by a common data field. **Relational Database Management Systems (RDBMS)** are used to create, update, and administer relational databases. Examples include Oracle, MySQL/MariaDB, and PostgreSQL; each enforces strict schemas for data management and is based on **Structured Query Language (SQL)**. Relational databases are widespread and commonplace largely due to their ease of access and ability to be scaled or extended.

Non-relational databases are classified on the basis of how they organize data. Unlike relational databases, they do not rely on traditional tables (fixed table schema) as storage structures or SQL-type management systems and thus are referred to as **NoSQL** (meaning non-SQL, or not only SQL). This flexibility facilitates Big Data management of various data formats found across the geoscience domain. Such organized data is referred to as a data warehouse or data lake when applied to storing very large amounts of data (**Big Data**). A complete discussion of these classification types can be found in Jatana et al. (2012). NoSQL databases are growing in popularity for use with geospatial data (Zang et al. 2014) and spatiotemporal data in energy applications such as photovoltaic power plants (Hu et al. 2017).

Machine Readable Data. The World Wide Web Consortium (W3C) has implemented metadata models that relate to language, meaning, or logic in an effort to make Internet data machine-readable. This effort exists as an extension of the web called the **Semantic Web** (French et al. 2015) which is a layered architecture comprising elements such as **Extensible Markup Language (XML)**. XML is a metalanguage specifying syntax without semantics. The **Resource Description Framework (RDF)**, a set of World Wide Web metadata specifications, appends ontological tags to Internet data in a pre-defined format (subject, predicate, and object), thereby providing semantic conceptual descriptions. The RDF is one example of how the Semantic Web has leveraged metadata to achieve machine readable information. **Web Ontology Language (OWL)** is another more powerful example. This is done through the use of structured ontologies required for data entry that classify data objects into nouns and relate data objects with verbs. This allows applications to process the information instead of simply presenting it. Software can be made to “read” and manipulate ontological structures. These can be serialized or converted to digital format for storage and transfer. Such Web services are particularly useful for data discovery exemplified by the **US Geological Survey (USGS)** that uses **JavaScript Object Notation (JSON)** to serialize the ontological information used in their National Digital Catalog (Runnels 2016).

And as computing advances to Exascale (10^{18} floating point operations per second = 1 exaFLOPS) (Kothe et al. 2019; Schulthess et al. 2019), there is an effort to enable

artificial intelligence (AI) and deep learning in an explicit Semantic Web implementation, based on the FAIR principles, that datasets, software, and models should all be **Findable, Accessible, Interoperable, and Reusable**, so as to enable machines to implement AI in modeling (Wilkinson et al. 2016, 2019; Fagnan et al. 2019).

Interaction with Computational Systems. The more common use of continuous integration in software engineering (CI) in combination with high-level software frameworks, such as TensorFlow2 and programming languages like R and Python, increased capacity of Central Processing Units (CPU), the expanded neural network capabilities now enabled in **graphic processing units (GPU)**, and **tensor processing units (TPU)**, has initiated a reengineering of many of the research and enterprise software solutions (Software framework – Wikipedia 2020; Jouppi et al. 2017). Cloud computing through platforms like Amazon’s AWS, Google’s GCP, and Microsoft’s AZURE is encouraging a transition to service-based cloud, hybrid cloud, and edge computing. These services provide cloud-based virtual computer systems or infrastructure as a service (**IaaS**), **Software As A Service (SaaS)**, and development **Platforms As A Service (PaaS)**. Such “aaS” paradigms provide sophisticated computing that offer flexibility while minimizing the need for expensive desktop or computer hardware. Figure 2 shows a generalized geotechnology trajectory and current migration of enterprise desktop software to the Cloud, accommodating the trend toward high-performance distributed computing and “aaS” paradigms.

The solution to current canonical geospatial problems is not just technical and scientific but also societal. For example, the world currently exists in a transitional state between fossil and renewable resources, a drive that ultimately pushes toward greener energy and a reduction in carbon footprint to help mitigate climate change. Juggling the science behind finding energy resources, the economics to develop them, and the policy solutions for fair governance, are nontrivial problems. R and Python can serve as interface languages that allow easy incorporation of machine learning, deep learning, and artificial intelligence, with GPUs (like in the AMD/Nvidia compute mentioned above) and deep learning frameworks (such as TensorFlow2 and Torch). This current and rapidly evolving technology addresses such immense challenges. Now this technology is accessible to geoscientists and other scientific communities (LeCun et al. 2015; Abadi et al. 2016; Paszke et al. 2019).

Current Investigation Examples

Geoscientists now have better insights into some of their canonical problems through the use of geoinformatics. The following are some examples of these investigations.

Planet Tectonism. New ways of understanding the cooling and transfer of heat from planet interiors and the impact on volcanic activity through heat pipe cooling are being investigated (Moore et al. 2017). While many proposed methods have been reliable, various efficiencies are required to optimize their use in modern computational systems and allow communication and comparison among different solvers. Working directly with common applications, an open-source parallel solver and discretization library has been proposed as a community tool supplying scalable, portable, reproducible performance toward novel science in regional and planet-scale geodynamics (Sanan et al. 2017). Scalable geospatial data analytics and other tools can be leveraged to inform efforts to recover valuable resources and plan for human needs (Klein et al. 2015).

Predicting Climate Change and the Associated Implications Using Geological Records. Open data access to climate information is now ubiquitous. Climate change is one of the most important hazardous impacts facing the future of human civilization (Schulthess et al. 2019). Recent geospatiotemporal analytics applied to the geography of climate change in California and Nevada using the PRISM and WorldClim interpolated climate databases shows the spatio-temporal relationships and heterogeneity at different scales. The research shows potential impacts of climate change and guides the evaluation and implementation of conservation strategies, which are identified as one of the main Exascale computing challenges (Ackerly et al. 2010). Another example is the Energy Exascale Earth System Model, in which the complex biogeochemistry and the geo-spatiotemporal aspects are used to simulate the historical carbon cycle dynamics, including carbon losses predicted in response to land use and land cover change and the responses of the carbon cycle to changes in climate (Burrows 2020).

Predicting Earthquakes

USGS developed an automated system for quickly estimating the fatality and economic loss from earthquakes and automatically assessing public response needs and informing government. **Prompt Assessment of Global Earthquake Response (PAGER)** uses XML, MySQL, and other geoinformatic components in the on-time relational database, to receive global information globally on seismological activity for measuring the severity of an earthquake, computing ground motion amplification maps, and ground shaking estimates within 30 min (Earle et al. 2009; Gundersen 2008).

Mapping and Analyzing Global Geospatial Data

Geospatial data can be hundreds of terabytes, or petabytes in size, use a variety of formats and projection methods, and

have multiple levels of resolution. These characteristics can impede data discovery from existing databases and require extensive data processing before applying analytical methods. For example, performing an analysis or building a model with data that has been referenced using a geographic coordinate system like WGS84 (global) and data using a projected coordinate system like NAD83 (south central Texas) can create dubious results if not rectified. Recent efforts to develop a geospatial platform for rapid retrieval and analysis of data from diverse, current, and historical databases are showing success. One such platform is the **Physical Analytics Integrated Repository and Services**, or **PAIRS** (Klein et al. 2015).

Geoinformatics: Discussion Topics

Open vs. Private Data. The digital landscape of geoscience crosses multiple disciplines both public and private facing. Data that are freely available to use is referred to as “open data,” following the concept of openness (Perens 2005) and its related concepts of open source software, open access, which contrast with “private” data that is proprietary. Open data provides scientists with a similar benefit experienced by programmers using open source technologies (i.e., large communities of talent working together). Before the advantages of open data can fully be harnessed, applications and separate datasets need to be interoperable and standards need to be addressed. Ongoing efforts are being made to standardize open data and make it more easily discoverable, supported by applications, and machine readable with minimal human intervention, as shown, for example, in the global dataset of wind and solar farms based on OpenStreetMap data (Wilkinson et al. 2016, 2019; Dunnett et al. 2020).

Private data are not necessarily subject to the same standards. Access to private data often requires legal non-disclosure or data use agreements with restrictions and prevents broader community support. The idea that knowledge growth can occur concurrently through public transparency and commercial privatization is problematic. The net effect can often result in a level of discord between industry and the public. Ultimately, the concept of open data and the privatization of data will hinge upon government policies (G8 2013; Obama 2013). The question of public transparency, knowledge growth, and free enterprise remains open, and many companies have identified ways to be commercially successful even with open source products, such as RedHat Linux (McMillan 2012).

Automation and Beyond. AI and automation are already influencing academic, governmental, and industrial institutions. The “Big Crew Change,” from baby boomer subject matter experts to GenX and Millennial young professionals, is well underway, and the geosciences are changing accordingly. Understanding the trend in technologies with the

purpose of predicting the future impact of these changes will help business leaders to define necessary skill sets (BHEF 2016). To be sustainable as a geoscientist without an education in data science and geoinformatics will be very challenging. Universities should incorporate these key disciplines into Earth science curricula in order to stay relevant and prepare for the inevitable transition from automation to robotics and autonomous computing. The question of the degree of automation and autonomy and the role of human supervision remains open.

Summary

Geoinformatics is about turning geoscience data and information into knowledge through the fusing of statistical and numerical methods with computer technologies. These processes are quantitative, which may seem unusual for a discipline whose origins are built largely on the pillars of qualitative analysis. Quantitative approaches, while not common in the early years, were highly impactful. From the beginnings of modern geoscience in the nineteenth century with Sir Charles Lyell, adoption of mathematics in the early to mid-twentieth century by pioneers like Griffiths, Krumbein, Sloss, and Matheron, to embracing geoscience software by researchers and industry practitioners in the mid-to-late twentieth century, the Earth sciences are squarely placed in the today's digital explosion. The construction and use of geoinformatic systems today are critical to solving twenty-first century geo-canonical problems. Understanding rocks and fluids at the nano-scale, modeling the impact of climate change, the prediction of earthquakes, and even data mining the vast storage of our historical qualitative data represent only some of the work ahead. To succeed, the geoscience community must recognize that our professional makeup must go well beyond our traditional domain specialities and include the continuous adaptation to geoinformatics which must be woven into the very nature of our common disciplines. As these systems merge with the expanding computational cloud and machine learning resources to form integrated geo-spatiotemporal data science and analytics, our future capabilities may be hard to imagine but will be impressive as they are brought to bear on the upcoming challenges.

Definition

The Geologic Time Scale (GTS) is the framework for deciphering and understanding the history of our planet. The steady increase in data, development of better methods and new procedures for actual dating and scaling of the rocks on Earth, and a refined relative scale with more defined units pose challenges to the methodology employed to calculate the GTS. This review explains the qualitative and quantitative methods used in GTS2020 with special emphasis on cubic splining. Relative to its ancestor GTS2012, the qualitative and quantitative methodology for GTS2020 is improved, uncertainty reduced, and stratigraphic resolution increased.

Introduction

The Geologic Time Scale (GTS) is the framework for deciphering and understanding the long and complex history of our planet, Earth. As Arthur Holmes, the father of the Geologic Time Scale, once wrote (Holmes 1965, p. 148): “To place all the scattered pages of earth history in their proper chronological order is by no means an easy task.” Ordering these pages, and understanding the physical, chemical, and biological processes that acted on them since Earth appeared and solidified more than 4 billion years ago, requires a detailed and accurate time scale. The time scale is the tool “par excellence” of the geological trade, and insight in its construction, strength, and limitations greatly enhances its function and utility. This calibration to linear time of the succession of events recorded in the rocks on Earth has three components:

1. The international stratigraphic divisions and their correlation in the global rock record
2. The means of measuring linear time or elapsed durations from the rock record
3. The methods of joining the two scales, the stratigraphic one and the linear one

For clarity and precision in international communication, the rock record of Earth’s history is subdivided into a “chronostratigraphic” scale of standardized global stratigraphic units, such as “Carboniferous,” “Eocene,” “*Zigzagiceras zigzag* ammonite zone,” or “polarity Chron M19r.” Unlike the continuous ticking clock of the “chronometric” scale (measured in years before the year 2000 AD), the chronostratigraphic scale is based on relative time units in which global reference points at boundary stratotypes define the limits of the main formalized units, such as “Permian.” The chronostratigraphic scale is an agreed convention, whereas its calibration to linear time, using radiometric and cyclostratigraphic methods, is a matter for discovery or estimation (Fig. 1).

In contrast to the Phanerozoic that has an agreed upon chronostratigraphic scale with formal stage boundary stratotypes, Precambrian stratigraphy is formally classified chronometrically, i.e., the base of each Precambrian eon, era, and period is assigned a numerical age. Below, we review geomathematical methods used in the Phanerozoic, spanning the last 538 million years. Most information and figures (except for new Fig. 5 and new Table 2) are from Agterberg et al. (2020), Agterberg et al. (2021), and Gradstein et al. (2020), and these will not be quoted again.

Figure 2 shows the current Phanerozoic Geologic Time Scale (GTS2020) with the Paleozoic, Mesozoic, and Cenozoic Eras and their subdivision into more than 10 periods and over 100 stages. The reason that quantitative methodology is

Geologic Time Scale Estimation, Fig. 1 The construction of a geologic time scale is the merger of a chronometric scale (measured in years) and a chronostratigraphic scale (formalized definitions of geologic stages, biostratigraphic zonation units, magnetic polarity zones, and other subdivisions of the rock record)

employed for geologic time scale building is the simple fact that only nine out of 100+ stage boundaries have a precise and accurate age date.

Methods and Ages

The methods used for the construction of Geologic Time Scale 2020 (GTS2020) integrate different techniques depending on the quality of data and methods available for different intervals, as shown schematically in Fig. 3. In this review we focus on cubic splining with composite standards from Ordovician through Devonian and cubic splining with orbital tuning and magnetostratigraphy for part of the Cretaceous and Jurassic.

GTS2020 time scale construction may be summarized as follows:

- Step 1. Construct an updated global chronostratigraphic scale for the Earth's rock record from standard outcrop sections and cored ocean drill cores.
- Step 2. Scale the updated chronostratigraphic scale with magnetostratigraphy or a composite standard technique.

The latter commonly takes average zone thickness from many sections as directly proportional to zone duration. It is applied for Paleozoic periods.

- Step 3. Identify key linear-age calibration levels for the chronostratigraphic scale using radiogenic isotope age dates, and/or apply astronomical tuning to cyclic sediment.
- Step 4. Interpolate the combined chronostratigraphic and chronometric scale, for example with a cubic spline that fits closest to data points with the lowest possible error. Such splines effectively bridge gaps in data along the linear scale or along the chronostratigraphic scale.
- Step 5. Calculate or estimate error bars on the combined chronostratigraphic and chronometric information to obtain a geologic time scale with estimates of uncertainty on stage boundary ages.

The first step, integrating multiple types of stratigraphic information in order to construct the chronostratigraphic scale, is the most time-consuming; it summarizes and synthesizes centuries of detailed geological research, while reconciling it with the most up-to-date information. The second step has lacked progress, with Periods like Cambrian, Devonian, Triassic, and part of Jurassic not yet having a composite standard of bio- and other events. The third step, identifying which radiogenic isotope and cycle-stratigraphic studies are to be used as the primary constraints for assigning linear ages, is the one that has been evolving most rapidly over the last decade. Historically, time scale building went from an exercise with few and relatively inaccurate radiogenic isotope dates, as used by Holmes (1947, 1960), to one with many dates with greatly varying analytical precision (like GTS89), to one with a majority of accurate and often precise dates (like GTS2020). The new philosophy, which was started with GTS2004 and continued in GTS2012 and GTS2020, is to select analytically precise radiogenic isotope dates with high stratigraphic resolution. More than 330 radiogenic isotope dates were thus selected for their reliability and stratigraphic importance to calibrate the geologic record in linear time.

The uncertainty on older stage boundaries systematically increases owing to potential systematic errors in the different radiogenic isotope methods, rather than to the analytical precision of the laboratory measurements. In this connection it is good to remember that biostratigraphic error is fossil event and fossil zone dependent, rather than age dependent.

Ages and durations of Cenozoic stages derived from orbital tuning are considered to be accurate to within a precession cycle (~20 kyr) assuming that all cycles are correctly identified, and that the theoretical astronomical-tuning for progressively older deposits is precise.

GEOLOGIC TIME SCALE 2020

Geologic Time Scale Estimation, Fig. 2 The new Geologic Time Scale 2020 (GTS2020)

Geologic Time Scale Estimation, Fig. 3 Methods used to construct Geologic Time Scale GTS2020 integrate different techniques depending on the quality of data available within different stratigraphic intervals

Conventions and Standards

Ages are given in years before “Present” (BP). To avoid a constantly changing datum, “Present” was fixed as AD 1950 (as in ^{14}C determinations), the date of the beginning of modern isotope dating research in laboratories around the world. For most geologists, this offset of official “Present” from “today” is not important. However, for archeologists and researchers into events during the Holocene (the past 11,500 years), the offset between the “BP” convention from radiogenic isotope laboratories and actual total elapsed calendar years becomes significant. The offset between the current year and “Present” has led many Holocene specialists to use a “BP2000,” which is relative to the year AD 2000. This practice is used in GTS2020 also.

For clarity, the linear age in years is abbreviated as “a” (for annum), and ages are measured in *ka*, *Ma*, or *Ga* for thousands, millions, or billions of years before present. Elapsed time or duration is abbreviated as “yr.” (for year), and longer durations in *kyr* or *myr*. Therefore, the Cenozoic began at 66 *Ma*, and spans 66 *Myr* (to the present day, defined as the year 2000 AD).

The *Ma* and *Myr* practice is confusing and inconsistent both internally and with respect to SI (Le Système international d’unités). As Holden et al. (2011) elegantly clarify (on behalf of IUPAC and IUGS), the same unit is used for absolute and relative measurements. This is in compliance

with quantity calculus, and its unit assignment for continuous and interval scales. Elapsed time or duration should also be abbreviated as in *ka* or *Ma*. Therefore, the Cenozoic began at 66 *Ma*, and spans or lasted 66 *Ma*. This is similar to the use of m (meters) for both absolute depth/distance and a depth/distance difference, and the use of $^{\circ}\text{C}$ for both temperature and temperature difference. For example, we say that the interval between two log markers in a borehole is 450 m thick, and starts 900 m below ground level. Despite this solution to an often fuzzy and confusing debate with respect to the notation of age and duration units in earth science, we (for now) stick to the same format as used in GTS2004, with both *Ma*, *ka* and *Myr*, *kyr* units.

The uncertainties in computed ages or durations are expressed as standard deviation (1-sigma or 68% confidence) or 2-sigma (95% confidence). The uncertainty is indicated by “ $\pm$ ” and will have implied units of thousands or millions of years as appropriate to the magnitude of the age. Therefore, an age cited as “124.6 $\pm$ 0.3 *Ma*” implies a 0.3 *Myr* uncertainty (2-sigma, unless specified as 1-sigma) on the 124.6 *Ma* date. We present the uncertainties ($\pm$) on summary graphics of the geologic time scale as 2-sigma (95% confidence) values.

Geologic time is measured in years, but the standard unit for time is the second *s*. Because the Earth’s rotation is not uniform, this “second” is not defined as a fraction (1/86400) of a solar day, but as the *atomic second*. The basic principle of the atomic clock is that electromagnetic waves of a particular frequency are emitted when an atomic transition occurs. In 1967, the Thirteenth General Conference on Weights and Measures defined the *atomic second* as the duration of 9,192,631,770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of cesium-133. This value was established to agree as closely as possible with the solar-day second. The frequency of 9,192,631,770 hertz (Hz) which the definition assigns to cesium radiation was carefully chosen to make it impossible, by any existing experimental evidence, to distinguish the atomic second from the ephemeris second based on the Earth’s motion. The advantage of having the atomic second as the unit of time in the International System of Units is the relative ease, in theory, for anyone to build and calibrate an atomic clock with a precision of 1 part per 10^{11} (or better). In practice, clocks are calibrated against broadcast time signals, with the frequency oscillations in hertz being the “pendulum” of the atomic time keeping device. One year is approximately 31.56 mega seconds (1 a $\approx$ 31.56 Ms).

The McKerrow Method

McKerrow et al. (1985) described the following type of method to construct a numerical time scale for the Ordovician, Silurian, and Devonian. Use was made of an iterative

construction involving a sequence of diagrams wherein the isotopic age of the sample was plotted along the x -axis and its stratigraphic age along the y -axis. They stated (p.73):

Most graphs are constructed with definite numerical scales along both the x and y axes; this is not the case with fig. 1, where only the horizontal (x) axis is numerical. The vertical (y) axis is a stratigraphic time scale, showing periods, series, stages and zones; the precise duration of each of these time divisions is unknown. In fact, the whole object of this documentation is to determine, as far as possible with the evidence available, what estimates can be given on the duration of these stratigraphic divisions. Thus, in the course of preparing this figure, we have constructed a series of graphs, each with slightly differing vertical scales, until we obtained a scale which allowed a straight line to pass through almost all the rectangles representing the analytical errors (2σ) and the stratigraphic uncertainties in the data we use.

In a later paper on the Ordovician time scale, Cooper (1999) used 14 analytically reliable and stratigraphically controlled high-resolution TIMS U–Pb zircon dates and a single Sm–Nd date. Adopting a modified version of the McKerrow method, Cooper plotted these Ordovician dates along a relative time scale that was then re-proportioned as necessary to achieve a good fit with a straight line obtained by linear regression. This method of relative shortening and lengthening of parts of the Ordovician time scale was based mainly on a comparison of sediment accumulation rates in widely different regions and, to some extent, on empirical re-proportioning. Agterberg (2002) subjected Cooper's (1999) data to spline fitting and found that the optimum smoothing factor corresponds to a straight-line fit. He then used Ripley's MLFR (Maximum Likelihood for Functional Relationship, Ripley and Thompson 1987) method to fit a straight line in which stratigraphic uncertainty was considered as well.

Smoothing Splines

A cubic-smoothing spline $f(x)$ is a sequence of cubic polynomials connecting “nodes” along the x -axis. These nodes are often set at the points where there are observed values. Spline curves are continuous at the nodes both in value of $f(x)$ and its first derivative $f'(x)$. Using index values $i = 1, 2, \dots, n$, a spline is fully determined from the values (x_i, y_i) , the standard deviations of the observed values $s(y_i)$, and a smoothing factor (SF) representing the square root of the average value of the squares of scaled residuals $r_i = (y_i - f(x_i))/s(y_i)$. All values (x_i, y_i) receive “weights” $w_i = 1/s^2(y_i)$. Special steps are taken to determine $f(x)$ at the first and last value of a sequence (cf. de Boor 1978; Wang 2011). In general, if all $s(y_i)$ values are unbiased, $SF \approx 1$, or SF is equal to a value slightly less than 1 (cf. Agterberg 1994, p. 874). If SF significantly exceeds 1, this suggests that some or all variances used are too small

(under-reported). Thus, the spline-fitting method can provide an independent method of assessing mutual consistency and average precision of published 2-sigma error bars.

The method of “leaving-out-one” cross-validation can be used to determine the optimum smoothing factor. In this method, all observed dates y_i , between the oldest and youngest one are successively left out from spline fitting with pre-selected trial values of SF. The result is $(n - 2)$ spline curves for each SF tried. The cross-validation value for any SF is the sum of squares of deviations between y_i and estimated values on the $(n - 2)$ spline curves with the same x_i values as y_i . The best SF has the smallest cross-validation value. It is noted that even if the cross-validation pattern shows a well-developed minimum at a value not close to 1, adoption of the optimum SF value instead of $SF = 1$ generally constitutes only a minor improvement of the spline curve. In Paleozoic applications, the optimum SF is generally smaller than 1. Setting $SF = 1$ would result in slightly smoother spline curves.

Unless its unit is consistently proportional to geologic time measured in millions of years, the numerical time scale resulting from spline fitting is not linearly related to the initial relative time scale. The latter is based on chronostratigraphic information such as relative thicknesses of biozones in Paleozoic periods or geographic locations of geomagnetic inversion points along ocean floor spreading profiles in the Late Mesozoic, to name a few examples. It is, however, linearly related to geologic time in millions of years. This allows for gradual changes over time in the original hypothetical process on the basis of which the initial relative time scale is constructed. For example, deviations from a straight line on a fitted spline curve may represent corrections of changes in rate of sedimentation, evolutionary change, or seafloor spreading.

In GTS2004, distances between successive points along the x -axis in x - y plots were not zero or close to zero. In the spline fitting, separate cubic polynomials are fitted between pairs of points, taking care that the resulting spline curve is continuous not only in age but also in its first derivative (changes in age). If distances between successive points are either zero or negligibly small, cubic polynomials cannot be fitted. Situations of this type arise when successive ash layers, which are close to one another in the field, are dated separately. This can result in problems in the spline fitting, especially when the leaving-one-out method is used for cross-validation. Such problems can be avoided by calculating the weighted average of dates with exactly or approximately the same values along the chronostratigraphic scale.

Smoothing Spline Software

In our GTS2020 applications, use was made of the *R*-program *smooth-spline* as implemented by B.D. Ripley and

M. Maechler in R. Stats Package version 3.6.0, with uncertainties based on total variances $s_t^2(y)$ or $s^2(y)$ if stratigraphic uncertainty could be neglected (also see next section). This program is freely available on the internet and widely used. Originally, the technique used now was based on code in the GAMBIT FORTRAN program by Hastie and Tibshirani (1990) using a smooth-spline function similar to the one described in Chambers and Hastie (1992).

The default application in R *smooth-spline* is application of a technique called generalized cross-validation (GCV). This technique was originally introduced by Wahba (1985) as a possible refinement of leaving-one-out cross-validation (CV). Differences between CV and GCV are discussed by Wang (2011). Usually the two methods give approximately the same results. However, in several of our applications to Paleozoic datasets, CV provided better results than GCV. This is because it is more robust in situations where relatively many points along the x-axis are close together or coinciding, even after application of the weighted average method described in the previous section. In such situations, CV produces a smooth curve whereas the GCV result may default to a set of straight-line segments connecting neighboring points. Best-fitting smooth curves were obtained by CV in all Paleozoic applications for GTS2020. Because of sparsity of dates for the Devonian, the spline curve for this period was assigned more uncertainty associated with it than the spline curves for the other periods.

As noted before, in some of our *smooth-spline* applications the initial output contained a warning that results (automatic *smooth-spline* estimation of CV) were not necessarily accurate because locally one or more successive x-values were equal or nearly equal to one another. In such situations, we have combined successive values (with the same position along the chronostratigraphic axis) with one another and the *smooth-spline* warning sign disappears. The method used to combine values with different values and their variances is based on elementary statistics (cf. Agterberg et al. 2020).

Devonian Example

Figure 4 shows the Devonian spline obtained for GTS2020 (Becker et al. 2020). It has significantly more associated uncertainty than the GTS2020 spline curves for the other Paleozoic periods. Table 1 shows corresponding input and output information. Almost all age dates are from U-Pb analyses using the TIMS method, and have less than 0.5 Ma external uncertainty. A number of the high-resolution age determinations are on ash layers with the same location along the horizontal (chronostratigraphic) scale. These ages were combined with one another, which reduces the 30+ radiogenic isotope age dates to 19. The chronostratigraphic

scale is based on thickness of over 20 Devonian conodont zones tentatively converted into Ma units (“Becker scale”). Several of the spline input values have significant uncertainties along the Becker scale, the result of uncertainty in linking some lower-resolution age dates to a specific conodont zone. Thus, total uncertainty associated with every input value is shown with a cross in Fig. 4. In general, these crosses should intersect the spline curve because they represent 95% confidence intervals along the two scales. Along the vertical scale, the underlying frequency distribution is assumed to be normal (Gaussian). For the horizontal scale it is assumed to be rectangular in shape. The weights in Table 1 assigned to the input data were obtained from variances $s_t^2(y) = s^2(x) + s^2(y)$. For other Paleozoic, $s^2(y)$ was used because stratigraphic uncertainty could be neglected.

The spline of Fig. 4 is based on 19 age points. Because there are 7 Devonian stages the number of age points expected to occur in two stages is $2 \times 19/7 = 5.43$. The Givetian and about half of the Frasnian and half of the Eifelian are without any age points. Using the binomial probability distribution, it can be shown that the probability of two adjoining stages being without any age points is about 0.0003. This is unlikely to occur if the age points are randomly distributed over geologic time. It is probable that within as well as immediately before and after the Givetian no or fewer ash layers were deposited. Such a relative lack of input dates would result in relatively greater uncertainty of the estimated spline values. In Agterberg et al. (2020), it is discussed in detail that uneven frequency distribution of input ages through time constituted a third source of uncertainty for Devonian stage boundary age determinations in GTS2012, in addition to the age determination and the chronostratigraphic uncertainties. Normally, the 95% half-confidence interval of a best-fitting spline curve is approximately hyperbolic in shape, widening toward the period boundaries, but for the Devonian there is extra widening of it at and near the Givetian because of the uneven frequency distribution of dates through time.

Curve fitting for the other Paleozoic periods is rather straightforward in that various techniques (smoothing spline, polynomial regression, or LOESS) yield more or less the same solutions. Moreover, 2-sigma values for successive age determinations are similar and it is possible to interpolate between these values to obtain reasonably good estimates of the 95% confidence intervals for the estimated stage boundary ages.

Paleozoic “Super-Spline”

The final GTS2020 age estimates for the Paleozoic stage boundaries are shown in Table 2 with their 2-sigma uncertainties. In this section a single spline curve is fitted to all age

Geologic Time Scale Estimation, Fig. 4 Devonian spline curve fitting results (based on GTS2020 Figure 22.14, Gradstein et al., 2012)

determinations for the Paleozoic by combining the chronostratigraphic scales for different periods. GST2020 results were obtained from spline curves fitted to the Ordovician-Silurian (OS), Devonian, and Carboniferous-Permian (CP), respectively. The Ordovician-Silurian and

Carboniferous-Permian splines are shown in Figs. 20.15c and 23.8 of Gradstein et al. (2020), respectively. The three separate horizontal chronostratigraphic scales for these splines are different but can be combined with one another into a single scale as follows.

The Devonian chronostratigraphic scale of Fig. 4 is taken as a starting point. In order to make the OS and CP chronostratigraphic scales compatible with it, two pairs of values were used: the base OS with age of 491.30 Ma on the GTS2020 time scale and CONOP value of 3.96 on the GTS2020 chronostratigraphic scale, and top CP with GTS2020 age of 251.22 Ma and 2658.97 on its GTS2020 chronostratigraphic scale. Because of this assumption, the original OS chronostratigraphic scale x' can be made compatible with the Devonian chronostratigraphic scale x by the linear transformation: $x = -489.37 - 0.7385 \cdot x'$. Likewise, the original CP chronostratigraphic scale can be subjected to the linear

transformation $x = -425.38 - 0.0655 \cdot x'$. These two linear transformations result in a single chronostratigraphic scale for the entire Paleozoic.

Figure 5 shows the result of spline fitting applied to the transformed dataset. The initial choice of using the Devonian chronostratigraphic scale x is arbitrary because any other linear scale could have been used for ensuring compatibility of the three original Paleozoic chronostratigraphic scales. For this reason, the unit for the horizontal scale in Fig. 5 was linearly transformed setting 0 for top of the Permian and 1 for base of the Ordovician.

The “super-spline” of Fig. 5 is used to obtain new estimates of all Paleozoic stage boundaries shown in Table 2 for comparison with the GTS2020 Paleozoic stage boundaries. Differences between the two types of estimates are given in the last column of Table 2 for comparison with GTS2020 2-sigma uncertainty estimates. These results show that only one of the estimated Paleozoic super-spline falls outside the ± 2 -sigma error band for its GTS2020 stage boundary

Geologic Time Scale Estimation, Fig. 5 Paleozoic “super-spline” as obtained by using the R-program *smooth-spline*

Geologic Time Scale

Estimation, Fig. 6 Best-fitting spline curve for the Late Jurassic – Early Cretaceous

estimate (base Tournaisian = Devonian-Carboniferous boundary). This indicates that cubic spline fitting is a flexible statistical method which is not subject to significant changes in number of age determinations per unit of time as occurred during the Paleozoic. The standard deviation of the differences in the last column of Table 2 is 0.80. This would be equivalent to an overall 2-sigma value of 1.6 Ma exceeding most 2-sigma values for the three separate splines used for GTS2020. It remains an open question whether or not the super-spline values of Table 2 are slightly better than the GTS2020 estimates.

Cretaceous and Jurassic Periods Cubic Spline

Spline fitting as applied to Paleozoic Periods in GTS2020 was also used to help obtain the GTS2020 Cretaceous and Jurassic time scales. The critical factor for the Early Cretaceous scale in GTS2020 is that a rather high-resolution U-Pb radiometric, geomagnetic, and cyclostratigraphic dataset is now available for the Tithonian through Barremian, not known during construction of GTS2012 (see discussion in Gradstein et al. 2020, Chapter 27).

Figure 6 is a plot of radiometric age against mid km M-sequence values that span 1198.2 km in total. In order to incorporate stratigraphic uncertainty, $s(x)$ was estimated for each distance value (x) by multiplying its sigma value by the ratio of total time interval (= 47.8 my) and the span of 1198.2 km in order to make use of the total variance equation: $s_t^2(y) = s^2(x) + s^2(y)$. The resulting smoothing spline is

almost exactly a straight line representing constant seafloor spreading. The spline curve in Fig. 6 is approximately a straight line with the equation $y = 0.0372 \cdot x + 122.77$, a result that can also be obtained by using the method of ordinary least squares. Degree of fit for this line could not be improved significantly by including higher-order terms in the polynomial equation fitted by the method of least squares.

Already Kent and Gradstein (1985) in their Cretaceous and Jurassic geochronology study for the Decade of North America Geology publications arrived at constant and linear spreading of the M-sequence as a reasonable template to interpolate the Oxfordian through Barremian time scale. Despite use of few tie points for the age versus M-sequence km plot, the Jurassic-Cretaceous boundary was interpolated by Kent and Gradstein (1985, 1986) at 144 Ma, only slightly older than the current 143.1 ± 0.6 Ma.

GTS2012 and GTS2020 differ from earlier geological time scales in that the ages post-Cretaceous stage boundaries are based on astrochronology-geochronology intercalibration. Increasingly, new information on Milankovitch cycles is becoming available for earlier stages. Ages of Late Cretaceous stage boundaries in GTS2020 are entirely based on Milankovitch cycles. The spline curve in Fig. 6 was used to obtain estimates of the Late Jurassic and Early Cretaceous stage boundaries. However, additional information on durations of Milankovitch cycles available for most of these stage boundaries was used to refine the estimates based on the spline curve of Fig. 6 (cf. Agterberg et al. 2020).

Summary

In our GTS2020 applications to estimate the age of stage boundaries use was made of the *R*-program *smooth-spline* with cross-validation (CV). Best-fitting smooth curves were obtained by CV in all Paleozoic applications for GTS2020 using a large number of radiogenic isotope age dates along the linear scale axis and detailed composite standards to independently scale the stages and zones along the chronostratigraphic axis. A specially constructed Paleozoic “super-spline” that combined the three individual spline curves for Ordovician-Silurian, Devonian, and Carboniferous-Permian did not significantly change the age estimates in GTS2020, and it remains an open question whether or not the super-spline values are slightly better than the GTS2020 estimates. Spline fitting as applied to Paleozoic Periods in GTS2020 was also used to help obtain the GTS2020 Cretaceous time scale. The critical factor for the Early Cretaceous scale in GTS2020 is that a rather high-resolution U-Pb radiometric, geomagnetic, and cyclostratigraphic dataset is now available for the Tithonian through Barremian, not known during construction of GTS2012. Information on durations of Milankovitch

cycles available for most of the Cretaceous stage boundaries was used to refine the estimates based on the spline curve.

Geomathematics

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

In its broadest sense, “geomathematics” includes all applications of mathematics to studies of the Earth excluding mathematics in geophysics. A synonym used more frequently is “mathematical geoscience.” Authors, teachers, and editors using the term “geomathematics” include Griffiths (1966a), Osborne (1969), Craig and Labovitz 1981, Merriam 1988, Zhao (1988), Bonham-Carter and Cheng 2008, and Agterberg (1974, 2014). These authors confined the term to applications involving geological studies of parts of the Earth’s crust. The modeling of geological processes that took place millions of years ago almost invariably requires consideration and estimation of uncertainties which are to be captured numerically by using probabilities. For this reason, most geomathematical applications continue to make extensive use of methods originally developed by mathematical statisticians. Recently, “big data” also has come to the foreground involving important new contributions by computer scientists (Zhao and Agterberg 2018).

Introduction

This author became involved in geomathematics because of his interest in mathematical statistics as a graduate student at the University of Utrecht. He joined the Geological Survey of Canada in 1962 as a “petrological statistician.” In 1965, he became the “geomathematician” in a section called “Geomathematics and Data Processing,” and in 1967, head of a “Geomathematics Section” in Ottawa which he headed until his retirement in 1996, although by then the section’s name had been changed into “Mathematical Applications in Geology.” As a term, “geomathematics” has never become as firmly established as the terms “geophysics” or “geochemistry.” “Mathematical geoscience” (formerly also known as “mathematical geology”) is a more widely used synonym of geomathematics. Outside the field of geology, Freedman et al. 2015 use the term “geomathematics” for mathematical applications restricted to the atmosphere. Also, in a different field of science, photogrammetrical engineers in France had the idea of abbreviating “géomatématique” to “géomatique” (Paradis 1981). This term was translated into “geomatics” in English and, since the 1980s, has become widely used for the treatment of (non-geological) geographical data and information.

The aim of this entry is to provide a historical perspective of geomathematics. Involvement by mathematical statisticians is discussed. Subsequently, applications more widely practiced in a number of different geoscience fields will constitute the main part of this entry. On the whole, the remarks to be made are of a historical nature although new challenges for future developments are outlined as well.

Relation of Geomathematics to Mathematical Statistics

Because of limited exposure of bedrock consisting of different rock types that were formed at different times during the history of the Earth, quantification of geological data generally is difficult. Originally most geologists, therefore, developed qualitative methods of approach using two- and three-dimensional graphics without the use of mathematics for geological problem-solving. According to Ronald Fisher (1954), geology with Lyell (1833) was originally evolving as a more quantitative science but, rapidly, opposition against this development grew to the extent that Lyell’s tables and statistical arguments for his subdivision of the Tertiary, which comprised 60 pages, were omitted from later editions of his book entitled *Principles of Geology*.

Until about 50 years ago, most geologists argued that the use of mathematical formulae is not appropriate for connecting the many different observations that can be made in outcrops of bedrock. They used qualitative conceptual models for guidance in their endeavors. As in the past, geological observations still have to be combined with one another to produce geological maps and their three-dimensional downward projections into the Earth’s crust. A good conceptual understanding of the mechanisms underlying the many different types of geological processes involved, therefore, remains essential. The results of different types of geological processes are often superimposed upon one another.

In spite these difficulties, the use of mathematics in geology gradually became more widespread along with the advance of scientific methods including the determination of chemical composition and numerical age of rock samples, and with the advent of digital computers. Mathematical geoscience commenced in earnest with the work of Krumbein (1936, 1939), Chayes (1956), Kolmogorov (1951), and Vistelius (1949). Geomathematical research by these pioneers and their successors included the modeling of processes that took place in geological time measured in millions of years. Merriam and Howarth (2004) arranged for the publication of biographical articles on the pioneers Matheron, Griffiths, Chayes, Reymont, Krumbein, and Vistelius in a special edition of *Earth Sciences History*.

An important development in geomathematics was the establishment in 1968 of the International Association for Mathematical Geology (IAMG). The initiative to create this new organization was taken by Richard Reymont of the University of Uppsala and Daniel Merriam at the Kansas Geological Survey. IAMG history is reviewed in several chapters of the handbook (Daya Sagar et al. 2018, eds.) that was published on the golden IAMG anniversary. The founders conceived this organization to be the offspring of two parents: International Union of Geological Sciences (IUGS) and International Statistical Institute (ISI). As a successful example to follow, they took the biometric society of quantitative biologists which was already in existence and continues to have a strong mathematical component.

Involvement by Mathematical Statisticians

When consulted by Reymont and Merriam, mathematical statisticians including John Tukey and M.S. Bartlett strongly supported the initiative to establish the IAMG. The mathematical statistician Geoffrey Watson became the first IAMG Vice President. He served on the executive committee of the organization. In 2007, the IAMG was renamed International Association for Mathematical Geosciences in recognition of the fact that many members are in disciplines other than geology.

Geomathematics is fortunate that influential mathematical statisticians of the last century were keenly interested in geology. As explained by Fisher Box (1978, p. 440), Ronald Fisher commenced giving regular talks on continental drift lamenting that geophysicists and geologists did not take seriously the theory of continental drift proposed by Alfred Wegener in 1912. Fisher (1954) made an important contribution to this theory by publishing a paper on statistical analysis of measurements of magnetization directions of basaltic lava flows (Fisher 1954). This technique allowed reconstruction of the movements of tectonic plates through geologic time. Geoscientists only accepted these ideas in the mid-1960s.

In 1966, the GSC allowed me to participate in the Advanced Statistical Seminar at the University of Wisconsin. During the Icebreaker, I was introduced to John Tukey who told me about his interest in geology. At this seminar, he presented “The Fast Fourier Transform, for Fun and Profit” (cf. Cooley and Tukey 1965). Back in Ottawa, I received a box filled with about 2000 IBM cards for running the FFT in one, two, or three dimensions on our mainframe computer. During the next 25 years, Tukey commented on my projects at the GSC in three of the approximately 800 publications he authored or co-authored (cf. Agterberg 2018a). Like Matheron, he was recognized at the 2001 ISI Congress in Seoul as one of the greatest mathematical statisticians alive during the second part of the twentieth century.

With Watson who had become Chair of the Princeton University Statistics Department, where Tukey was a professor, he attended the 1969 Geostatistics Colloquium organized by Dan Merriam in Lawrence, Kansas, that also had Matheron, Krumbein, and Serra as participants. Watson owned a cottage on Blood Hill near Elizabethville in the Adirondacks, New York State, not too far from Ottawa. In those days, the GSC maintained a pool of cars with the words “Geological Survey of Canada” in big letters on the sides. I could use one if these cars to visit Watson during weekends. On one occasion I drove Geof and some of his family members to Princeton where Tukey spotted us on the campus. He started laughing and pointing his finger at Watson suggesting that Geof had become a “geologist.” Watson stimulated me to improve my mathematical skills. Pointing out some errors in a review of Agterberg (1974) he had, somewhat sarcastically, remarked that one could see I was not trained as a mathematical statistician. However, he would have granted me an MSc degree in this discipline.

Subsequently, I worked hard on my mathematics. In 1983, I organized a geomathematical workshop at the GSC in Ottawa at which Geof Watson, Fred Bookstein, Jean Serra, and Benoit Mandelbrot were among the presenters. Mandelbrot who had coined the word “fractal,” like Matheron, originally was a student of Paul Lévy at the École Polytechnique in Paris. Both Matheron’s and Mandelbrot’s theoretical developments contain elements of Lévy’s approach to mathematical statistics. Other participants included the directors of Carleton University’s Centre of Mathematical Statistics who shortly afterwards invited me to become an Adjunct Professor in their Mathematics Department. Personally, I have always felt that mathematical statistics offered more challenges than conventional geology, although this remains a scientific discipline in its own right.

Relation of Geomathematics to the Geosciences

Applications in nine different geoscience subfields will be discussed in the next subsections concerned with, respectively: geostatistics, mineral resource estimation, compositional data analysis, directional features, mathematical morphology, quantitative stratigraphy, geologic time scale estimation, and fractals and multifractals and lognormal and Pareto frequency distributions. These are all areas where mathematics makes major contributions.

Geostatistics

Current applications of geostatistics and kriging are adequately explained in other entries in this encyclopedia. Some historical comments are as follows: Originally, Georges Matheron (1955a, 1963) made an important contribution to geoscience by introducing the idea of regionalized random

variables that randomly change their values in three-dimensional space. It is not widely known that Matheron (1955b) started his career in 1954 as a geologist in the French Geological Survey (BRGM). One of his first publications (Matheron 1955b) is concerned with the Gara Gjbilet oolitic iron deposit in Algeria. It is a standard geological publication with a folded geological map in the back and detailed descriptions of the stratigraphy, structure, and genesis of this deposit of Early Devonian age. It can be assumed that, indirectly, the spatial continuity of bedrock probably led Matheron to largely disregard the use of most statistical methods that were in existence at that time.

Originally writing in French, Matheron coined the term “géostatistique,” later translated into “geostatistics” in English. This term became more widely used than “geomathematics.” Although geostatistics is a form of mathematical geoscience, its practitioners are to a large extent mining engineers who apply geostatistical techniques for problem-solving in three-dimensional space, generally without consideration of the various processes of change that may have taken place during geologic time when the objects of study were created. Matheron (1955a)’s first geostatistical paper accompanies a translation into French of Krige (1951)’s pioneering quantitative valuation of Witwatersrand gold mines in South Africa. Somewhat later this led Matheron (1963) to introduce the term “krigeage” that in English became “kriging.”

Mineral Resource Estimation

After geostatistics, that is mainly concerned with ore reserve estimation, mineral resource estimation continues to be a topic of primary interest in geomathematics. Originally, Allais (1957) assumed that (1) the spatial distribution of large mineral deposits in the Sahara Desert satisfies the Poisson distribution for number of deposits per unit area and (2) the total dollar values of these deposits satisfy a lognormal distribution. Griffiths (1966b) pointed out that mineral deposits tend to cluster and proposed that the negative binomial distribution provides a better model than the Poisson distribution. Various early models along these lines were reviewed by Harris (1984) including a novel approach by Brinck (1974) that can be characterized as multifractal (see section on Fractals and Multifractals). It is noted here that, contrary to the Poisson or negative binomial distribution, fractal or multifractal distributions for point patterns do not have a constant mean value for number of points per unit of area. This topic will be discussed in more detail in the section on fractals and multifractals.

Other methods of mathematical statistics modified for use in the geosciences continue to play an important role in quantitative mineral resource evaluation. An objective of this branch of geoscience is to produce mineral potential maps representing, in one way or another, the probabilities

of occurrences of undiscovered mineral deposits of different types and their characteristic features such as size and grade. There usually are great uncertainties associated with the results of these efforts. It is well-known that the process of searching for an economically viable new ore or hydrocarbon discovery often resembles the process of looking for a needle in a haystack.

However, different types of mineral deposits including oil and gas fields are the end products of processes that not only required favorable environments for hosting the ore but also probably left important clues in the vicinities of the deposits themselves. These clues include geophysical and geochemical anomalies. It is the task of the quantitative geoscientist to evaluate in probabilistic terms the mineral potential of large or small study areas. The geo-input for this work consists of geological, geophysical, geochemical, and remote sensing data. These need to be transformed into variables relevant to the occurrences of the known deposits so that probabilities of occurrence of both known and unknown deposits can be estimated. One method for this is Weight-of-Evidence modeling (Agterberg 1989; Bonham-Carter 1994; Cheng 2008). This method quickly results in probabilistic maps with potential targets for further mineral exploration in places with no or fewer than expected ore deposits. Finally, properties of the known deposits such as their sizes and grades could be used to estimate additional expected values that amplify the maps representing the probabilities of occurrence. This presents a new topic for further research (cf. Agterberg 2014, Fig. 4.16).

Compositional Data Analysis

Geological variables, especially for rock composition data, are subject to various constraints that affect the shapes of their frequency distributions and their relations with other variables. Closed-number systems such as the major oxides measured on rock samples provide a primary example as first pointed out by Chayes (1971) showing that silica (SiO_2) content generally is negatively correlated with other major oxides in collections of rock samples, simply because it usually is the dominant rock constituent, and increases in concentration values for other major oxides must be accompanied by decreases in silica. Pearson (1897) had already pointed out that spurious correlations between variables can arise if they are functions of random variables. Aitchison (1986) developed the powerful new methodology of compositional data for variables in closed-number systems. The book by Pawlowsky-Glahn and Buccianti (2011) contains many more recent examples of application.

Directional Features

Almost invariably when one inspects an outcrop of bedrock anywhere, some of the geological features that can be observed show directional features that can be measured. Planar features such as bedding or schistosity have a strike

and dip; linear features such as minor fold axes or non-spherical pebbles have a direction of plunge and dip. These directions often are displayed on geological maps or collectively in diagrams for larger areas. Not surprisingly, much of the statistical theory for treatment of directional features has been developed on the basis of geological data. An early example of this is the study of preferred orientation of pebbles in a conglomerate by Krumbein (1939), who measured the direction in which each pebble was oriented on a scale from 0° to 360°, then doubled the angle, took the average for all pebbles considered, and then divided this average by 2 to obtain a “best” estimate of preferred orientation. This indirect procedure avoids the problem that the direction of elongation of an elongated pebble cannot be distinguished from its counterpart in the opposite direction.

Later, when methods of statistical inference including analysis of variance had become available, geologists, including Potter and Olson (1954), applied these methods to their directional data. However, the methods they used were based on the assumption that the measurements are normally distributed. A problem of application of such methods to directional features is that the circle is used for measurement so that the system is not open but closed. Personally, I became involved in the statistical analysis of directional features when as a graduate student I commenced work on minor fold axes in quartz phyllites in the Italian Alps. Measurements collected in small areas of about 1 km² approximately satisfy a two-dimensional normal distribution on the sphere, which presents a problem of closure analogous to the closure problem for 2-D directional features on the circle. Results of this approach are shown in my PhD thesis (Agterberg 1961) that later was made available on the internet by the University of Utrecht. Subsequent refinements of the methods used to construct regional patterns in this publication are summarized in Agterberg (2014, Chapter 8).

The PhD thesis helped me to obtain a postdoctorate fellowship at the University of Wisconsin in Madison in 1961 where my main task was to help a graduate student to statistically analyze directional measurements of sedimentary features (Agterberg and Briggs 1963). William Krumbein was a reviewer of this paper in which we applied conventional analysis of variance to the data. In a footnote in the manuscript, I had pointed out that this procedure was permissible because for increasingly small variance the circular normal distribution approaches the normal (Gaussian) distribution. Krumbein felt that this statement was a significant finding which deserved further explanation in a section rather than a footnote. Two of his PhD students (Jones and James 1969) continued the use of conventional analysis of variance. However, it was not known to us at the time that Watson (1960) had developed methods of statistical inference including variance analysis providing good approximations based on the isotropic 2-D frequency distribution proposed by Fisher

(1954). Numbers of degrees of freedom in Watson’s methods remain approximate but are better than if the 2-D Gaussian distribution would be used as the basic statistical model. Statistical analysis of spherical data is discussed in detail by Fisher et al. (1987).

Mathematical Morphology

In 1968, Georges Matheron established the Centre de Morphologie Mathématique in Fontainebleau, as a research institute of the École des Mines de Paris. Jean Serra was his close collaborator. Watson has done much to make Matheron’s work in the fields of geostatistics and mathematical morphology better known in the English-speaking world. He persuaded Matheron (1975) to write his book on random sets and integral geometry. At the time Watson told me that there would be only three people in the world able to understand this book from beginning to end.

Since the upper part of the Earth’s crust consists of numerous geological bodies that seem to be in part randomly located with respect to one another, it is somewhat surprising that mathematical geologists have paid relatively little attention to mathematical morphology. The examples in publications by Sagar (2013, 2018) show that good new results can be obtained by increased usage of this methodology.

Quantitative Stratigraphy

Stratigraphy is the branch of geology concerned with the study of rock layers (strata) and layering (stratification) which is a common property of sedimentary and some types of volcanic rocks. Stratigraphy has two related subfields: lithostratigraphy (lithologic stratigraphy) and biostratigraphy (study of layers characterized by fossils). It was mentioned before that Lyell (1833) used a statistical method to subdivide in what was then termed the Tertiary into stages. For large samples, he determined the proportions for species still alive today. For example, the “Pleistocene” contains most species that had not become extinct. This was the earliest example of quantitative biostratigraphy. Early examples of quantitative lithostratigraphy are reviewed by Schwarzacher (1975). This field covers a wide range of methods of time series analysis applied to lithostratigraphic sections.

My book on automated stratigraphic correlation (Agterberg 1990) is mainly concerned with methods to correlate stratigraphic sections at different geographic locations (e.g., using microfossils in drill cores from deep wells drilled in sedimentary basins). One computer program for this method developed in close collaboration with Felix Gradstein was called RASC for ranking and scaling of biostratigraphic events (Gradstein and Agterberg 1982). Among paleontologists, it has led to the term “rascing” (cf. Agterberg and Gradstein 1996), that continues to be used.

Dan Merriam helped to establish several quantitative projects within the framework of the International Geological

Correlation Programme (IGCP) co-sponsored by UNESCO and the IUGS. It included IGCP Project 163 (1977–1984): “IGBA” (IGneous data Base) led by Felix Chayes. IGCP Project 148 (1976–1983): “Quantitative Stratigraphy” was originally led by John Cubitt, but in 1977, I took over as its director. Every year we held an international meeting and there were several national meetings as well. There also was an international quantitative stratigraphy short course informally known as the “traveling circus” that eventually was eventually given in nine different countries. These activities have helped to spread the use of methods of quantitative stratigraphy.

Geologic Time Scale Estimation

The international geologic time scale (GTS), which provides ages measured in millions of years (Ma) with their uncertainties for the boundaries between the approximately 100 stratigraphic stages that have been defined and mutually correlated worldwide, is based on geomathematical methods (Gradstein et al. 2020). The chronogram method originally used by Harland et al. (1982, 1990) for this purpose is suitable for estimation of the age of chronostratigraphic boundaries from a radiometric database when the age estimates of most rock samples used for age determination are subject to significant relative uncertainty. Inconsistencies in the vicinity of chronostratigraphic boundaries can then be ascribed to imprecision of the age determination method.

Cox and Dalrymple (1967) originally developed an approach for estimating the ages of Cenozoic chron boundaries from inconsistent K–Ar age determinations of basaltic rocks. Harland et al. (1982, 1990) adopted this method in their calculations of ages of stage boundaries. The basic principle of the approach is as follows: assuming a hypothetical trial age for an observed chronostratigraphic boundary, rock samples from above this boundary should be younger, and those below it should be older. An inconsistent date is either an older date for a rock sample known to be younger than the trial date, or a younger date for a sample known to be older. The difference between each inconsistent date and the trial age can be standardized by dividing it by the standard deviation of the inconsistent date. Thus, relatively imprecise dates receive less weight than more precise dates. Standardized differences between inconsistent dates and trial age can be squared and the sum of squares (written as E^2) determined for all inconsistent dates corresponding to the same trial age.

The time scale chronograms constructed by Harland et al. (1982) were U-shaped plots of E^2 against different trial ages spaced at narrow time intervals. Optimum choice of age was set at the trial age where E^2 was a minimum. Agterberg (1988) made the following improvement to this method. In addition to inconsistent dates, there are generally more consistent dates for any trial age selected for a chronostratigraphic boundary. The statistical maximum likelihood method was used to

combine consistent with inconsistent dates resulting in an improved estimate of the age of the chronostratigraphic boundary considered. It involves using an iterate process clearly explained by Rao (1973). In this type of calculation, inconsistent dates receive more weight than consistent dates. Generally, the improvement resulting from using consistent dates in addition to the inconsistent dates is relatively minor. However, when there are relatively few dates, use of the consistent dates yields significantly better results. The log-likelihood function is beehive-shaped. For examples, see Gradstein et al. (1995).

A general disadvantage of chronogram methods is that the relative stratigraphic position of the sample is generalized with respect to stage boundaries that are relatively far apart in time. Relative stratigraphic position of one sample with respect to another within the same stage is not considered. A better approach is to incorporate relative stratigraphic positions of fewer samples for which more precise age determinations are available. Current geochronological (U–Pb and Ar–Ar) dating methods have become about 10 times as precise as the earlier methods. It implies that weights in statistical methods given to more recent age determinations are now roughly 100 times greater than in the 1980s. In 1983, the traveling circus mentioned in the preceding section was at the Indian Institute of Technology in Kharagpur. The lecturers included Geof Watson, who in 2 h filled an extra wide blackboard entirely with equations on the relationship between kriging and interpolation splines. It is doubtful that anybody in the audience (including me) could understand what he was talking about. Later I spent significant time comprehending his subsequent paper on the subject (Watson 1984) and I commenced using smoothing splines for geological time scales (Agterberg 1988). Early history of time scale construction methods is reviewed in more detail in Agterberg (2014).

Splining was used extensively for the international geologic times scales published during the past 20 years (Gradstein et al. 2020). Initially, computer programs used to fit smoothing splines were based on FORTRAN code published by de Boor (1978). The leaving-one-out jackknife method was employed to estimate the optimum smoothing factor. This method was also used in GTS2020 but now use is made of the R-program *smooth-spline* as implemented by B.D. Ripley and M. Maechler in R.Stats Package version 3.6.0 made generally available in 2019 (cf. Agterberg et al. 2020).

Fractals and Multifractals

The term “fractal” was introduced by Mandelbrot (1977) to characterize natural phenomena with non-integer dimensions. Other influential books with geoscience applications on this subject were Federer (1988), Korvin (1992), Stoyan and Stoyan (1994), and Turcotte (1997). Later it was found that many phenomena originally thought to be fractals are

multifractals that are physically intertwined fractals with different dimensions (see, e.g., Mandelbrot 1989, or Lovejoy and Schertzer 2007). In his doctoral thesis, Qiuming Cheng (1994; also see Cheng and Agterberg 1996) showed that point patterns previously thought to have a constant mean number of points per unit of area can be modeled as multifractals. In Agterberg (2014, 2018b), it is illustrated that worldwide patterns of ore deposits of different genetic types compiled by Singer and Menzie (2004) for so-called permissive tracts are probably multifractal although they can be approximated by fractals as well.

Mandelbrot (1989) has pointed out that the so-called model of de Wijs (1951) was the first multifractal conceived. This model was taken by Brinck (1974) to describe the worldwide distributions of uranium and several other metals. Later it was used by Agterberg (2018b) for the same purpose.

Lognormal and Pareto Frequency Distributions

Both the lognormal and the Pareto frequency distribution have played important roles in the geosciences, particularly in geochemistry and economic geology. Both are “stable” forms that arise as the end products of generating processes that may involve other types of frequency distributions (Lévy 1925; also see Mandelbrot 1977). In the past, authors have preferred one type of frequency distribution above the other. For example, Turcotte (1997) favors the Pareto distribution, whereas Ahrens (1953) proposed the lognormal as a fundamental law of geochemistry. Both models provided excellent degree of fit for relatively small data sets. During the past 20 years, a new model called the Pareto-lognormal distribution has been developed that is lognormal for most of the data but Pareto in the tails (cf. Kleiber and Kotz 2003).

Patiño Douce (2018) has compiled a large data base of metallic mineral deposits. Various metals including Cu, Zn, Pb, Ni, Mo, Au, and Ag are approximately lognormally distributed but have upper and lower tails that are clearly Pareto type (see, e.g., Agterberg 2020). A major difference between the Pareto-lognormal distributions for metallic mineral deposits and the Pareto-lognormal distributions for incomes described by Kleiber and Kotz (2003) is that in the upper tails where there are fewer than expected large mineral deposits which are smaller than the largest deposits that satisfy the Pareto model. A possible explanation for this departure from Pareto-lognormality is that the largest deposits have better developed geophysical and other anomalies, and were economically the most desirable targets (Agterberg 2020).

Summary

Although the term “geomathematics” has been used by a number of authors, a better-known synonym is “mathematical

geoscience.” In this entry, the emphasis was on historical uses of mathematics in several subfields of the Earth Sciences. It has been pointed out that geologists were slow to adopt mathematical methods in their approach to develop complete two- and three-dimensional representations of the upper parts of the Earth’s crust. However, with the advent of new computer-based methods for graphics and “big data” analysis, the quantitative approach to geological problem-solving is being practiced increasingly widely.

Geomatics

Rifaat Abdalla

Department of Earth Sciences, College of Science, Sultan Qaboos University, Al-Khoudh, Muscat, Oman

Definition

Geomatics is defined as a systematic, multidisciplinary, integrated science that is dealing with systems and technologies for collecting, storing, integrating, modeling, analyzing, retrieving, transforming, displaying, and distributing spatially georeferenced data from different measurements with well-defined precision and accuracy characteristics and continuity and in a digital format. The term geomatics consists of two parts: geo, which means Earth, and “matics” in the sense of informatics. Hence, geomatics refers to the science of geoinformatics. Geomatics is based on a number of basic sciences and technologies, which include computer science, remote sensing, geospatial information systems (GIS), photogrammetry, cartography, global navigation satellite system (GNSS), and decision support systems (DSS) (Barrile et al. 2019).

Geomatic Components

Land Surveying

Survey science is the science that professionals and researchers use to locate the natural and human features present on or under the Earth’s surface and the representation

of these appearances on traditional (printed) or digital maps (using the computer).

There are several divisions of the types of survey applications, whether in terms of the field of use or in terms of the purpose of the survey work or in terms of the survey device used and the survey sections (Deren 2017), which has classified survey into terrestrial survey with subcategories of geodetic and plane survey, photogrammetry, hydrographic survey, and astronomical survey. Figure 1 summarizes the classification of survey operations.

Survey Measurements

Survey measurements are of three types, namely, distance measurements, angle measurements, and contour measurements (elevation). The distance measurement could be measured with a tape or electronically, while the angles can be measured with the help of theodolite equipment. Contours can be measured with level and height and through the leveling process.

Geodesy

Geodesy is the science of measuring and mapping the Earth’s surface. Geodesy is also concerned in determining the shape and size of the Earth, based on accurate measurements such as distance measurements, star positioning, and gravitational force measurements. Geodesy can be categorized into (1) mathematical, (2) satellite, (3) ground measurements, and (4) astronomical.

Photogrammetry

Photogrammetry is a branch of surveying that allows measuring landmarks without approaching them, as measurements are made through images, whether aerial photos or satellite images. According to Smith et al. (2016), photogrammetry is characterized by (a) making accurate measurements, (b) covering a large area of the Earth’s surface (producing maps from aerial photography is less time-consuming and less costly than a ground survey), (c) making stereograms and topographic mapping, (d) tracking time changes, (e) clarifying features and features that the human eye cannot see, (f) highlighting underground features, and (H) accentuating spatial features in remote areas.

Digital photogrammetry is a technological development of traditional photographic scanning methods based on computers in the stages of imaging, analysis, and measurement of aerial photos, and it is characterized by several characteristics, including high spatial resolution, image acquisition speed, automatic operation and analysis, fast image reproduction, and lower cost (Woodget et al. 2017).

Remote Sensing

Remote sensing attempts for deriving information about a specific target or location located at a distance from the

Geomatics, Fig. 1 Classification of survey operations

sensor. Remote sensing is characterized by the ability to sense the same geographical area repeatedly over a period of a span of time ranging from several hours to several weeks. This allows for obtaining updated imagery periodically, thus allowing for following up the dynamic geographical phenomena.

Remote sensing information acquisition consists of three stages, data collection, data processing, and data interpretation. Based on the type of sensor, it is classified into passive sensors, where the source of energy is transmitted from the sensor, and active sensors, in which the sensor uses its own energy. The remote sensors can be divided in terms of the number of electromagnetic energy ranges that are dealt with and recorded, so the sensors can be divided into the following (Steenweg et al. 2017): optical, where there are four types of sensors including panchromatic (black and white), multispectral, super spectral, and hyperspectral. Radio detection and ranging (radar) is a type of the active sensors and is divided into single frequency and multifrequency.

Global Navigation Satellite Systems (GNSS)

GNSS or global navigation satellite system is the standard generic term for satellite navigation systems that provide autonomous geospatial positioning with global coverage. It offers three-dimensional coordinates of fixed or moving targets anywhere on the Earth and under any climatic conditions. GNSS is integration of different positioning systems, which are the global positioning system (GPS), the global navigation satellite system (GLONASS) developed by Russia, and GALELIO, which is developed by the European Space Agency. The basic idea in these systems depends on the satellites sending radio waves that are received and recorded through special ground receivers and then calculating the coordinates of the position of the receiver, and these calculations depend on knowing the coordinates of the satellite itself, depending on the prior knowledge of the satellite's orbit in space. For instance, the GPS location coordinates are determined by calculating the distance between the device and the satellite by knowing the time between the moment the signal is sent from the satellite and the moment it is received in the receiver (Pasku et al. 2017). The GPS as a major component

of the GNSS has three segments: the space segment, the control segment, and the user segment. It offers two main types of services: standard positioning service and the precise positioning service.

Among the many important applications of the GPS are (1) producing accurate and digital topographic and detailed maps, (2) hydrography and nautical chart development, (3) determining the ground adjustment marks for images and videos, (4) spatial data collection for geographic information systems, and (5) portable map systems.

Geographic Information Systems (GIS)

GISs are an effective set of tools for collecting, storing, analyzing, and displaying spatial data using specific data models that replicates the real world. These models can be for a specific purpose or for a general purpose. The representation of spatial data depends on (1) spatial data that includes the location or coordinates attributed to a specific system, (2) nonspatial data which provide attribute information related to features such as area and type, and (3) spatial relationships between representations or topology of features. GIS is subdivided into different types including (Jia et al. 2017) land information systems (LIS), topographic information systems (TIS), and building information modeling (BIM). There are many advantages of GIS, including (1) merging spatial and nonspatial information into a single database, (2) high ability to analyze spatial and nonspatial data, (3) the ability to visualize spatial information, (4) helping to make decisions, and (5) data documentation with specific specifications. Data sources for GIS are from paper and digital maps, remotely sensed imagery, photogrammetry data, nautical charts, and bathymetric surveys in addition to nonspatial data from statistical sources. The GIS represents the phenomena in a certain spot on the surface of the Earth through several layers. Each layer represents a specific type of geographical phenomena, for example, when representing a neighborhood of a particular city, streets are drawn in a layer, buildings in the second layer, and trees in the third layer. If all these layers are visualized at the same time, a representation of the real scene in this area is obtained. There

Geomatics, Fig. 2 GIS data types and products

are two broad data models in GIS: (a) vector data, which can be found in form of point, line, and polygon, and (b) raster data, which can be formed in pixel-based products. GIS data components and analysis are shown in Fig. 2.

Cartography

Cartography is the science of providing a description of the shape and size of the Earth and its natural and human features and showing this description on maps (Craib 2017). Cartographic tasks are (1) drawing, draw the features and geographical features with precision; (2) representation, the accurate appearances of features (projection); (3) generalization, the selection of features and best mode for representation; and (4) map design, finding the most appropriate way to allow for visualizing the features easily.

According to cartography, a map is a flat and symbolic approximate representation of the surface of the Earth or parts of it. This requires models to represent the shape of the Earth through specific symbols. The elements of map content include (A) basic elements (the title of the map, map legend, coordinate grid, and map projection) and (B) secondary elements (data sources, graphic charts, tables, inset maps, date of the map, and producer of the map). Key components of a map are based on survey (measurement) and on the type and selection of spatial data. It also depends on data standardization and data generalization, converting the points of the surface of the Earth to its equivalent on a reference surface by relying on reference coordinate systems and representing the reference surface of the Earth on the map through mathematical models that allow the representation of landmarks or points on the map or on the computer screen. Perception of the map through symbols is important in allowing for real-world representation.

Digital cartography is distinguished from traditional cartography by the main characteristic of using digital data. This allows for data storage, manipulation, and easier and faster presentation. It provides the ability to control the scale of the map to achieve the desired level of detail. Digital cartography deals with 3D coordinates. It enables the user to quickly automate selection, classification, and statistics and spatial analysis of targets or features. Users are able to add additional

dimensions like the fourth dimension (time) to spatial variables by dealing with different data for the same spatial region, which allows tracking the temporal changes of spatial phenomena in an accurate digital manner.

Innovations in Geomatics

New technologies have influenced the shape of geomatics in the last decade. Although the domain of geomatics in itself is a modern domain, many advancements in technologies have further contributed to the innovation in geomatics. This can be summarized by more portable and handheld geomatic devices, for visualization, field data collection, and integration with other equipment in the field. The second leap in geomatic technologies is advanced integration in instrumentation. Unmanned aerial vehicles (UAVs) can now perform sophisticated geomatic operations through different onboard geomatic sensors, whether it be imaging sensors or surveying sensors, to provide timely solutions on field operations. The third leap on geomatic innovation is the advancement in hydrography and underwater imaging. Hydrography tools and equipment are getting more integrated, more robust, and more affordable, which allow for additional advancement in geomatic applications. Figure 3 is showing new advanced mobile handheld devices for field surveying that integrates GIS, GPS, remote sensing, and land surveying devices in one portable instrument.

Geomatic Applications

There are many applications for geomatics. It can be used in surveying, to produce ground constant network maps whether in the form of single or multiple drawing scale with different geodetic references. The advanced geomatic technology applies high-accuracy and high-precision special surveying equipment, for instance, portable thermal imaging devices and portable laser range finders. Specific applications of remote sensing are numerous; some of the most important are production of detailed and contour maps, urban studies (land use) transportation network planning, follow-up on natural disasters, climatic studies, searching for natural resources, and geological studies. Remote sensing military applications monitor what is happening on the ground in a specific area on a daily basis (or less). The use of UAV drones provides fast acquisition and high-resolution imagery, while some satellites record videos, not just visuals. Remote sensing is one of the most accurate and fastest ways to obtain spatial information. When starting precision agriculture project, the use of remote sensing in determining and studying the qualitative distribution of soil use of RS to develop high-resolution DEM for the region during work. Remote sensing

Geomatics, Fig. 3 Showing new advanced mobile handheld devices for field surveying

can also be used to monitor crop growth throughout the growing season. Using remote sensing is effective to determine proper watering times and plant need for water. Remote sensing is used to monitor soil moisture condition and to track weather, rain, and drought characteristics. Remote sensing is also usable in detection of plant diseases using near-infrared imaging. Estimation of the crop size at the end of the growing season can be achieved using remote sensing.

There are numerous applications for GIS; some of these applications are for (1) creating maps, utilities and services, public facilities, and planning; (2) urban and regional planning; (3) Earth science and the exploration for natural resources; (4) environment-related application; (5) agriculture-related projects; (6) historical, archaeological, and tourism applications; and (7) military applications. Real-time security applications such as police-ambulance-civil defense use real-time detection of sites. It allows for determining the shortest/fastest route for rescue vehicles and observes for huge crowds. Specific applications such as precision agriculture depend on the availability of modern, accurate maps at a

scale suitable for its purposes. Detailed and topographic maps in addition to updated maps of everything that is happening on the ground, after each quarterly crop: update topographic maps (terrain). It depends on the availability of spatial and nonspatial information in a timely manner about plants, soil, and climate in order to provide the farmers with the necessary instructions on soil management and the best time for agricultural management operations to reach the best yield.

Summary

Geomatics is interdisciplinary science that incorporates computer science, where all data sources, processing, and algorithms are based upon. Geodesy, which provides approximation for the shape and area of the Earth or large portions of it. Surveying, whether land surveying or hydrographic surveying in which measurements about the Earth surface and subsurface are taken. Cartography is the science

of making map, whether in the old artistic way or in the new digital way of composing maps. Photogrammetry is the science of taking measurements out of remotely sensed high-resolution aerial photos or imagery. It is of two parts, softcopy and hardcopy photogrammetry. Remote sensing is the science of extracting imagery from the Earth surface, without being in a direct contact with it. GNSS is related to the global navigation satellite system, which comprises the global positioning system (GPS) and other systems that provide accurate location data. Laser scanning system provides 3D surface capture. Geographic information system (GIS) provides a system for managing, processing, and manipulation of georeferenced data. Decision support system (DSS) is used to support decision-makers with efficient and informed aid for effective decision-making process.

Geomechanics

Pejman Tahmasebi

College of Engineering and Applied Science, University of Wyoming, Laramie, WY, USA

Definition

Geomechanics is a branch of science where the mechanical behavior of rock and soil is studied. More precisely, the deformation of rock/soil is investigated in geomechanics through which one can better manage the risk. This field brings the geology and mechanics of materials together to analyze the physical behaviors and deformations in an analytical way.

Introduction

Geomechanics influence can be seen in a wide range of fields such as radioactive waste disposal, carbon dioxide sequestration in the subsurface to avoid the negative effect of these gas on the atmosphere, natural gas storages, energy resources, mining, and natural hazards (e.g., earthquake, landslide, volcano, and flood). Understanding the mechanics of geomaterials and their application in the service of humanity is vital. In geomechanics, we are interested to describe the behavior of geological environments to internal and external forces, which is often achieved by describing the state of stress and strain history.

It also has been widely shown that the lack of geomechanical considerations has a significant drawback while its absence can cause damages, including financial losses and/or humans life. There are many historical accidents that could be avoided if they were studied geomechanically before it happens. An example is the St. Francis Dam disaster (Begnudelli and Sanders 2007; Rogers 2006); this gravity curved dam was built in 1926 and the building process took 2 years. The height of this dam was 205 feet. In 1928, the dam failed, 432 people died, and property damage was estimated to be around seven million dollars. The insufficient foundation stress support and reactivation of a landslide near the dam were recognized as the cause of the failure, which could be estimated using accurate geomechanical modeling. A couple of other disasters led engineers to recognize the importance of geomechanical studies during the design of projects.

In a similar fashion, subsurface geomechanics has also witnessed huge progress, which refers to cases where the

depth of the case study does not exceed 10 km. Knowledge of the stress in such depths is the essential element that leads engineers to have comprehensive geomechanical models. If the stress concentrated around, for example, the well/tunnel becomes higher than the rock's strength, the rock system will fail. The use of geomechanics, thus, is to estimate where and when the failure happens. Consequently, the associated risk and recommendations can be provided to lower the threat. Similarly, a fault can slip when effective normal stress becomes lower than the exerted shear normal stress. These variations of stress can be initiated from a variety of sources, such as deposition, fluid injection/withdrawal, thermal effects, and other tectonic variations, which altogether vary with time. Thus, geomechanical behaviors should be studied with time and they manifest a dynamic process. The same conclusion is also valid for geomaterials' strength properties as they change with time as well. Given the above-described situation with geological environments, pre-existing stresses always exist. Therefore, it is critical that such variabilities (e.g., stress, strength, pressure) are characterized before making any intervention, which is often referred to as geological history. Based on mentioned facts, we have to know the fundamental stresses to enhance our knowledge for modeling purposes. In subsurface systems, such elements always experience compressive stress, which depends on factors such as pore pressure, depth, and the geological characteristics of soil and rock layers above the element. Briefly, three characteristics are describing the stress field:

- Stress at depth: it is considered as a basic knowledge that could help engineers solve practical problems in geomechanics.
- In situ stress field at depth and scales relation: with analyzing different data from different sources, these scales important can be found.
- Many numerical and experimental techniques can help us measure and estimate stress magnitude in the stress fields.

In this section, the subsurface stresses and pore pressure and stress tensor will be discussed briefly.

Subsurface Stresses and Pore Pressure

Subsurface Stresses

Stress in rock systems varies with depth. Unlike fluid pressure, the stress in rocks depends on many elements such as the properties of the upper layers and other geological conditions (i.e., tectonic stresses). In general, stress (σ) can be formulated as a force (F) acting on an area (A):

$$\sigma = \frac{F}{A}. \quad (1)$$

Geomechanics, Fig. 1 Schematic of forces on a small element in subsurface systems

In the element that is shown in Fig. 1, with volume $\delta x \times \delta y \times \delta z$, the summation of all vertical forces is zero in an equilibrium condition, $\sum F = 0$. Thus:

$$S_v A + \rho_{bulk} \delta x \delta y \delta z g - S_v A - \Delta S_v A = 0 \quad (2)$$

$$\Delta S_v = \rho_{bulk} g \delta z \quad (3)$$

which in turn:

$$\int_0^{S_v(z)} dS_v = \int_0^z \rho_{bulk} g \delta z. \quad (4)$$

where S_v is total vertical stress, ρ_{bulk} is the density of bulk material (density of water and rock), and g is the gravitational acceleration.

Effective stress (σ_v) is defined as the difference between total vertical stress and pore pressure P_p , which is mostly compressive. Effective stress is an important quantity using which one can analyze the stress in rocks and soils better. The effective stress is given by:

$$\sigma_v = S_v - P_p \quad (5)$$

Pore Pressure

In geomechanics, in particular for geosystems, one must always consider the effect of fluid on the total stress. Depending on the amount of fluid, pore pressure can make strengthen or weaken the system. For example, exceeding a certain amount of fluid can result in liquefaction and large geological disasters. Similarly, granular particles can stick together when a small amount of fluid exists. An example of this situation can be found in castle structures generated using sand on beaches. Thus, understanding the effect of pore pressure on stress is very critical. Generally speaking, pore pressure, in large-scale systems, can be divided into two groups: hydrostatic and non-hydrostatic. In many cases, estimation of the pore pressure is challenging since there are lots of pores connected. In lower depths, pore pressure increases with the depth hydrostatically. It should be noted that the stress can also vary with the rock properties and the type of materials. Similarly, the rock type can also control the pore pressure. For instance, low permeability barriers can cause overpressure. Pore pressure measurement development with depth is shown in Fig. 2 graphically. The overpressure parameter (λ_p) is defined as the ratio of pore pressure to the total vertical stress:

$$\lambda_p = \frac{P_p}{S_v} \quad (6)$$

Vertical Stress

The vertical stress solely is not enough to evaluate the state of solid. But, the stress applied to an element can be defined in form of principal stress. The principal stress is all stresses applied perpendicular to each other in three directions. If there

is no shear stress on the plane, the stress is named principal stress. In most cases, the total vertical stress is considered principal stress. In this particular situation, the other principal stresses are horizontal. All stresses can be formed as a symmetric 3×3 matrix, which is called a stress tensor. Since the stress tensor is symmetric, there are three eigenvalues, and they are called principal stresses since there is no shear stress on those planes. Mostly, the stress elements should be rotated to reach the principal stress.

Research Path of Geomechanics

The importance of geomechanics for problems related to geomaterials has been shown extensively, which has led to conducting more research both experimentally and numerically. Most of the initial studies and analytical solutions were developed for particular problems, and they often contain various user/material-dependent parameters. With the introduction of high-speed computers, numerical investigations have become more popular. Indeed, the recent progress in computational capabilities has led to developing methods that were not applicable before for large-scale systems, such as the finite element method (FEM), finite volume method (FVM), etc. Although an enormous improvement can be seen in the experimental techniques, numerical simulations are developing rapidly.

One of the fields that has witnessed the abovementioned advancement is developing various Lagrangian approaches. The discrete element method (DEM) is one of the well-known Lagrangian techniques used in geomechanics where each particle's trajectory is estimated and forces applied on particles are calculated based on Newton's second law (O'Sullivan 2011, 2015). To achieve a more accurate and comprehensive representation of particles and the mechanical behavior of the system, a wide range of forces are added to the DEM formulations, including cohesion, and DLVO theory.

As discussed earlier, the pore pressure effect should not be neglected as it can tremendously change the spectrum of final deformation. Computational fluid dynamic (CFD), which is an Eulerian method, has been added to the Lagrangian techniques (i.e., DEM) and is known as CFD-DEM coupling (Tahmasebi and Kamrava 2019; Zhang and Tahmasebi 2019; Zhao and Shan 2013). Moreover, other important physics can also be added to the above framework and develop THMC (thermo-hydro-mechanical-chemical) modeling (Zhang et al. 2015).

Conclusion

Geomechanical modeling, in particular those related to sub-surface systems, is one of the complex and important systems, which affect humans' life, and their accurate modeling can be to reduce the risk while reducing the cost. This branch of

Geomechanics, Fig. 2 Pore pressure development with depth

science and engineering has been applied in many fields related to geomaterials. To have a fundamental knowledge of geomechanics, one should understand the stress for the target system. For example, CO₂ leakage and sequestration are some of the topics that require an extensive application of geomechanical modeling, and it can help to reduce the deformation and safe preserving of carbon in subsurface systems. With the recent demand for electric cars and also renewable energy, mining will also experience more challenges in terms of slope modeling when more minerals are extracted.

Geoscience Signal Extraction

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

In various geoscience applications, a series of observed data can be considered to be the sum of a signal and random noise. Usually, the noise can be eliminated in order to retain the signal. “White” noise results in a value less than one at the origin of the correlogram, or as the so-called “nugget effect” in the variogram of geostatistics. “Red” noise is best evaluated in the frequency domain where white noise shows as a horizontal line whereas red noise results in a straight line that dips in the direction of the frequency axis. In most applications of geoscience signal extraction, the signal occurs at or

around a single point. However, especially in stratigraphy, the signal can be sinusoidal. A primary example of this is the Milankovitch cycle that not only controlled the occurrences of ice ages but also those of many older periodical stratigraphic phenomena as well. Finally, the signal can be a meaningful pattern involving many points at which observations are obscured by superimposed random noise. Examples of these different types of signals will be given in this entry.

Introduction

Suppose a series of observed values (x_k) is the sum of two series: signal (s_k) and white noise (n_k) with $k = 1, 2, \dots, n$. The autocovariance functions of such series can be written as $\Gamma_x(h)$, $\Gamma_s(h)$, and $\Gamma_n(h)$ satisfying the relations: $\Gamma_n(h) = 0$ if $h \neq 0$ and $\Gamma_x(h) = \Gamma_s(h) + \Gamma_n(h)$. Suppose that $\Gamma_x(0) = 1$ and $\Gamma_n(0) = c$. Let $F(h)$ denote a filter to which the record must be subjected in order to obtain the signal: $s_k = \int_{-\infty}^{\infty} F(h)x(k+h)dh$. Then, $\Gamma_s(h) = \int_{-\infty}^{\infty} F(h+\tau)\Gamma_s(\tau)d\tau + \int_{-\infty}^{\infty} F(h+\tau)\Gamma_n(\tau)d\tau$ or $\Gamma_s(h) = \int_{-\infty}^{\infty} F(h+\tau)\Gamma_s(\tau)d\tau + (1-c)F(h)$. Fourier transformation of both sides gives: $G(\omega) = \Phi(\omega) \cdot G(\omega) + (1-c)\Phi(\omega)$ where $G(\omega) = \int_{-\infty}^{\infty} \Gamma_h \cos \omega h dh$ and $\Phi(\omega) = \int_{-\infty}^{\infty} F_h \cos \omega h dh$. It follows that: $\Phi(\omega) = \frac{G(\omega)}{G(\omega) + (1-c)}$. The filter $F(h)$ can then be found by taking the inverse Fourier transform: $F(h) = \int_{-\infty}^{\infty} \Phi(\omega) \cos \omega h d\omega$. When $\Gamma_x(h) = \exp(-a \cdot |h|)$, then: $G(\omega) = \frac{2ac}{a^2 + c^2}$ and $F(h) = \frac{ac}{\pi p^2(1-c)} \int_{-\infty}^{\infty} \frac{1}{\frac{\omega^2}{p^2} + 1} \cos \omega h d\omega$ where $p = [a^2 + 2ac/(1-c)]^{0.5}$. It follows that: $F(h) = q \cdot \exp(-p \cdot |h|)$ where $q = ac/[(1-c) \cdot p]$. Two methods most frequently used to help extract the signal are using the autocovariance function and spectral analysis. The latter method has the advantage that its successive values are stochastically independent. In geostatistics, it is common to use the variogram which is closely related to the autocovariance.

The autocovariance of an ordered sequence of random variables is defined as $\Gamma_h = E[(X_k - \mu) \cdot (X_{k+h} - \mu)]$. The sample autocovariance for n values can be estimated by: $C_h = \frac{1}{n-h} \sum_{k=1}^{n-h} (x_k - \bar{x})(x_{k+h} - \bar{x})$ where the mean value $\bar{x} = \frac{1}{n} \sum_{k=1}^n x_k$. The autocorrelation function satisfies $\rho_h = \Gamma_h/\Gamma_0 = \Gamma_h/\sigma^2$, and the sample autocorrelation coefficient is $r_h = C_h/C_0$. Together, the r_h values form a so-called “correlogram.” Wiener’s (1933) theorem of autocorrelation states that the power spectrum satisfies: $\varphi(\omega) = \int_{-\infty}^{\infty} \rho_h e^{-i\omega h} dh$. Since ρ_h is even, $\varphi(\omega) = \int_{-\infty}^{\infty} \rho_h \cos \omega h dh$. After some manipulation, it follows that: $F(h) = q \cdot \exp(-p \cdot |h|)$ where $q = ac/[(1-c) \cdot p]$ (cf. (Yaglom 1962; Agterberg 1967). In the next section, the power spectral density $P(f)$ will be computed as:

Geoscience Signal Extraction,
Fig. 1 Pulacayo Mine zinc concentration values for 118 2-m channel samples along horizontal drift (original data from de Wijs 1951). Sampling interval is 2 m. “signal” was retained after filtering out “white noise”. (Source: Agterberg 2012, Fig. 1)

$$P(f) = C_0 + \sum_{k=1}^m W(k) C_k \cos 2\pi k f \quad \text{with } W(k) = \frac{1}{2} (1 + \cos \pi k / m).$$

The weighting function $W(k)$ defines a cosine-shaped lag window for the autocovariance function whose use is called “hanning” (cf. Blackman and Tukey 1958).

The purpose of hanning is that individual values $P(f)$ can be considered to estimate a smoothed version of the underlying true spectrum. For more explanations of why this procedure can be useful, see Blackman and Tukey (1958). The power spectrum $P(f)$ can be regarded as a decomposition of all variability in a series in terms of components of the variance for narrow frequency bands. Smoothing operations such as hanning significantly improve their estimation from the autocovariances by eliminating distortions.

Pulacayo Mine and Main KTB Borehole Examples

De Wijs (1951) used a series of 118 zinc concentration values from samples taken at a regular interval along a horizontal drift in the Pulacayo Mine in Bolivia (Fig. 1). Average zinc value is 15.61%. This series has been used extensively in later studies by many authors including Matheron (1962), Tukey (1970), Chen et al. (2007), Lovejoy and Schertzer (2007), Cheng (2014), and Agterberg (2014). The geological setting of the Pulacayo Mine and genesis of this sphalerite-quartz ore deposit are briefly described in a scientific communication by Pinto-Vásquez (1993).

The zinc values used by de Wijs (1951) are for channel samples cut at 2-m intervals across the steeply dipping Tajo vein along a horizontal drift on the 446-m level. These channel samples were cut over a standard width of 1.30 m corresponding to expected mining width. Figure 1 shows both the original zinc values and the signal extracted from them. The method used for this smoothing was described in detail in Agterberg (1974). It assumes that each zinc value is the sum of a “signal” component for continuous change along the series plus a random white-noise component. Together these two components were assumed to produce an autocorrelation function of the type $\rho_h = c \cdot \exp(-ah)$ where h represents distance along the drift (see Fig. 2) and $c < 1$ and a are constants. Several authors including Matheron (1962) preferred to work with logarithmically transformed metal concentration values. The best-fitting autocorrelation functions for original and logarithmically transformed zinc values are practically the same for the Pulacayo deposit. Figure 3 indicates that the noise also can be assumed to be red (cf. Tukey 1970), because white noise would have resulted in an approximately horizontal line in the frequency domain.

Figure 4 shows 2706 copper concentration values taken at 2-m intervals along the Main German Continental Deep Drilling Program Borehole (abbreviated to KTB, cf. Goff and Hollinger 1999), along with mean values for 101-m long segments of drill core. Statistical analysis for this example is discussed in more detail in Agterberg (2012). The long series of copper values was divided into three subseries, each about 2 km in length. Figure 5 shows that, over short distances, the logarithmically transformed (original) copper values satisfy

Geoscience Signal Extraction, Fig. 2 Estimated autocorrelation coefficients for original data shown in Fig. 1 (diamonds) and logarithmically transformed zinc concentration values, shown together with best-fitting negative exponential autocorrelation functions. The curves for original and logarithmically transformed data coincide approximately. (Source: Agterberg 2012)

Geoscience Signal Extraction, Fig. 3 Periodogram of the 118 zinc concentration values with quadratic curve fitted by least squares (Logarithms base 10). The negative exponential curve of Fig. 1 would show as a horizontal line in this kind of plot. Obviously, the assumption that the noise is “red” instead of “white” is better because it would result in a straight line with a negative dip. (Source: Agterberg 2012, Fig. 25)

approximately a signal-plus-white-noise model of the type $\rho_h = c \cdot \exp(-ah)$ with approximately the same value of a along the entire length of this deep borehole. To some extent, the white noise in this example is due to the measurement errors of the copper content determination method used.

Spectral Analysis: Glacial Lake Barlow-Ojibway Example

Glacial varves that consist of alternate silt and clay layers, because of their presumed annual nature (silt deposited during

Geoscience Signal Extraction, Fig. 4 Copper concentration (ppm) values along Main KTB bore-hole together with average copper concentration values for 101 m long segments of drill-core. Locally the original data deviate strongly from the moving average. (Source: Agterberg 2012, Fig. 15)

Geoscience Signal Extraction, Fig. 5 Correlograms for three segments of series of original copper values shown in Fig. 4. Series 2 (for depths between 2 and 4 km) and series 3 (for depths between 4 and 5.54 km) exponential autocorrelation functions similar to the one for depths from 0.05 to 2 km except for difference in Log Rho intercept. (Source: Agterberg 2012, Fig. 16)

the summers; clay during the winters), have attracted the attention of geologists as a geochronological tool. Anderson and Koopmans (1965) were among the first to apply spectral analysis to varves.

Lake Barlow-Ojibway was a late-glacial water body that formed approximately 11,000 years ago during the retreat of the Late Wisconsin ice sheet in northern Ontario and western Quebec. The lake, in its maximum extent, measured about

960 km in the east-west and 240 km in the north-south direction. The most extensive deposit formed in it was the sheet-like body of varves which extends uninterruptedly across the Hudson Bay – St. Lawrence divide. More detailed geological background with references to earlier work is given in Agterberg and Banerjee (1969). Kuenen (1951) had proposed a mechanism of varve deposition by annual

turbidity currents with rapid silt deposition during the summer followed by slow clay deposition during the winter.

In total, Agterberg and Banerjee (1969) statistically analyzed 4310 thickness measurements from eight sections (Fig. 6). Six of these sections were aligned with respect to one another on the basis of the “datum” which is a relatively abrupt increase in thickness of the varves. This datum coincides with the Cochrane readvance of the land-ice about 8000 years ago (Antevs 1925; Hughes 1955). In the longest series (No. 4 with 537 silt-clay couplets), silt layers near the bottom are about ten times as thick as those near the top. The clay layers near the top are about three times thinner than those near the bottom. A logarithmic transformation was

desirable in order to ensure that variations in thickness are of the same magnitude in parts of the series that are relatively thick and relatively thin, respectively. For example, the sum of squared silt thickness data, on which measures of variability such as the variance are based, amounts to 1037.2 cm^2 for series 4. The first 100 values in this series contribute 91.99% and the last 100 values only 0.02% to this total sum of squares that is based on all 537 data. If no logarithmic transformation would be applied to the observations, results from a statistical study would be largely determined by variations in the thicker parts of the series, whereas variations in the thinner parts of the series would have a negligibly small effect on the end results. The logarithmic transformation stabilizes the

Geoscience Signal Extraction, Fig. 6 Filtered curves for varve thickness data, series 1-8, Lake Barlow-Ojibway. Solid lines denote silt thickness; broken lines are for clay thickness. (a) A is boundary between sandy and silty facies; (b) B is boundary between silty and diamictic

facies, s: slumped intervals, G gaps in records with 5–10 varves missing. Width of 95% confidence belt is shown at end of each series. (Source: Agterberg and Banerjee 1969, Fig. 7)

Geoscience Signal Extraction, Fig. 7 Power spectra for four longest series ($n > 250$). Frequency scale is shown in spectrum for series 4 only. 95% confidence belts are also shown. (Source: Agterberg and Banerjee 1969, Fig. 5)

variance. The ratio of the variances for the first and last sets of 100 silt values for series 4 is 33.6, but after logarithmic transformation, it reduces to 1.5.

The varve time series are not stationary in that, for example, both mean silt and clay layer thickness tend to decrease with time. As a rule, such decreases are stronger in the silt than in the clay. Observed varve series are incomplete because

thicknesses could not be measured in places where slumped layers occur. These places are shown as “s” in Fig. 6. Some gaps where a larger number of varves is probably missing are identified as “G” in this figure. In total, as much as 10% of total number of varves may be missing in some series including series 4.

Varve-thickness data, like tree-rings, provide a sensitive tool to measure very small temperature fluctuations on Earth. Power spectra are shown in Fig. 7 for the four longest series ($n > 250$). All spectra commence with a strong peak close to the origin for low-frequency waves representing long-term variations or “trends.” For 20-year and lesser periods, the spectra tend to flatten out. It is likely that the peaks for shorter periods are not exclusively caused by random variations but are partly due to weak periodical phenomena. The first peak for silt (S_1 in Fig. 7) occurs at a period of about 14 years in all four spectra. Along with its 14-year multiples, it also shows up clearly in the correlogram for residuals from the Series 4 linear trend (see Fig. 8).

A 14-year periodicity of this type is not known to occur in glacial deposits elsewhere in the world. A possible explanation was offered by Schove (1972). This author suggested climatological variations due to solilunar cycles as the cause. Brier (1968) had shown that solilunar cycles produce significant tidal effects in the atmosphere at 13.5 and 27 years. According to Schove (1972), silt components of varves are suitable for study of solilunar cycles as affect in the summer months of June and July.

The 13.5-year (163 calendar months) cyclicity is the beat period between the calendar month (30.44 days) and the synodic month (29.5 days). These two cycles are in phase with one another every 163 months, and both then are approximately in phase with the cycle arising from the anomalistic month (27.55 days). The synodic cycle is the period from one new moon to the next and the anomalistic cycle that from one

perigee to the next. These two cycles are most important in determining the magnitude of the solilunar gravitational tide, which has significant effects on monthly weather conditions according to Brier (1968).

Peaks in power spectra often are followed by secondary peaks that tend to be equally spaced along the frequency scale. These may represent “harmonics” reflecting deviations from sinusoidal shape of the periodic phenomenon (*cf.* Schwarzacher 1967). This phenomenon is most conspicuous for clay in series 4 where there are nine peaks, all of which are multiples of frequency 0.05 or a value slightly larger than 0.05. This probably reflects the 22-year and 11-year sunspot cycles that have been found in varves elsewhere in the world (Schove 1983; Berry 1987) and in other laminated sediments, e.g., in marl-limestone couplets belonging to the Late Campanian *Radotruncana calcarata* Zone (Wagreich et al. 2012). Sunspot cycles have variable duration, but on average, they last 11 years. The 22-year cycle is due to alternation of stronger and weaker 11-year cycles.

Unit Vector Fields

In the final example, the signal is a two-dimensional pattern that only becomes clearly visible after the elimination of white noise. It is concerned with so-called B-axes for Hercynian minor folds and schistosity planes in quartzphyllites belonging to the crystalline basement of the Italian Dolomites. During Alpine orogeny, these *s*-planes were not only refolded, but there were also large-scale sliding movements along the Hercynian schistosity resulting in various kinds of Alpine rotations of the Hercynian B-axes. Elimination of local random disturbances helps to outline the resulting regional deformation patterns. This example is for measurements of B-axes in quartzphyllites in the San Stefano area east of the Dolomites.

Figure 9 (after Agterberg 1985) shows original measurements or average B-axes for (100 m × 100 m) squares on the left side in comparison with unit vector means on the right side that are based on much larger samples obtained by combining all measurements from within circular neighborhoods with radii of 1 km (solid arrow heads) or 2 km (open arrowheads). Local random deviations from the regional pattern are eliminated when the mean vectors are used because these are based on many more original measurements. Structural interpretation of the change in average dip of the B-axes is as follows. The ESE-striking schistosity-planes and the B-axes are Hercynian in age. During Alpine orogeny, the San Stefano crystalline containing them formed the core of an anticlinal structure in which the Hercynian schistosity planes were reactivated. The trace of the resulting Alpine anticlinal structure with NW-SE trending axial plane intersects the approximately WNW-ESE striking Hercynian schistosity planes.

Fitted curve satisfies stochastic differential equation of second order Markov process. (Source: Agterberg and Banerjee 1969, Fig. 9)

Geoscience Signal Extraction, Fig. 9 San Stefano area. Unit of distance for coordinates of the grid is 10 km. Length of arrow is proportional to cosine of angle of dip (Maximum arrow length is 1 km). Left side: B-axes and unit vector means in (100 m × 100 m)

cells. Unit vector means of B-axes located within circles with 1 km radius (solid arrow heads) and 2 km radius (open arrow heads). (Source: Agterberg 2012, Fig. 4)

Summary and Conclusions

Geoscience signal extraction is one of the most important statistical methods in geoscience. For many different reasons including measurement errors, various features are obscured when they are observed at the surface of the Earth. White and red noise are the main causes of this obscuration. In this entry, various methods were discussed to combine multiple observations to eliminate random noise in order to extract meaningful signals. These signals either occur at or in the vicinity of points in geological time or three-dimensional space; they can be sinusoidal or regional in their extent. The examples given were (1) element concentration values in orebodies and ordinary rocks, (2) cyclical phenomena in sedimentary rocks, and (3) orogenic deformation patterns in structural geology.

Digital ecosystem

Definition

A “Geosciences Digital Ecosystem” is a digital ecosystem whose functional utility is the generation and sharing of knowledge on the Earth.

In other words, a “Geosciences Digital Ecosystem” is a system of systems that applies the digital ecosystem paradigm

to model the complex collaborative and competitive social domain dealing with the generation of knowledge on the Earth planet.

Stemming from the concept of natural ecosystem (Blew 1996), the Digital Ecosystem paradigm focuses on a holistic view of a diversity of autonomous organizations (i.e., corresponding to the “biotic” component), sharing (as the “abiotic” component) a common digital environment and a set of digital resources to survive, thrive, and coevolve. Digital ecosystems, as their digital counterparts, aim at emulating the self-organizing properties of biological ecosystems, which are considered to be robust, self-organizing, and scalable architectures that can automatically solve complex, dynamic problems (Briscoe and De Wilde 2006).

An archetypal example of geoscience digital ecosystem is represented by a set of public and private autonomous stakeholders, which deal with the generation of information and knowledge on the Earth, loosely cooperating on the Internet environment and complementing each other by sharing datasets, analytical software, and computing capacities (Nativi et al. 2021).

Essential Concepts and Components

Ubiquitous connectivity, datafication, sensing, and computing virtualization are the new and powerful capacities offered by a digitally transformed society. Industry, science, academia, and humanity must leverage these new instruments to further develop distributed knowledge systems and engage multiple, diverse, and autonomous stakeholders, for a better monitoring and understanding of the Earth systems and phenomena. This innovative paradigm, consisting of heterogeneous entities interacting through loosely coupled connections to generate and share knowledge on our environment is known as geosciences digital ecosystem. As in the case of the more mature business and software digital ecosystems (Moore 1996; Jansen et al. 2013), a geoscience digital ecosystem can be a temporary collaboration (for a recognized and timely limited common value) and, sometimes, an opportunistic one.

The geosciences digital ecosystem represents an innovative model to develop distributed knowledge platforms to study the Earth behavior, by engaging multiple and diverse stakeholders interacting in a common and powerful virtual environment, the cyber-physical sphere. It replaces and brings up to date the concepts of Spatial Data Infrastructures (SDI) we saw developing in the 1990s and 2000s. The geosciences digital ecosystem paradigm promises to address the traditional SDI technological limitations (e.g., technology evolution and the pragmatic interoperability) (Nativi et al. 2021) and more importantly the non-technological ones: the data strategies diversity, the different degrees of openness

characterizing the infrastructure constituent systems, the services and products ownership concerns, the pursuing of different enterprise utilities, and the business models heterogeneity. With the advent of big data and the consequent data-driven artificial intelligence algorithms and cloud computing, there is no longer a distinction between the local/physical digital environment and the network/virtual one as most organizations store and process their data on the network itself, which has become the common and virtual development platform for all the stakeholders.

By applying the digital ecosystem paradigm, complex and distributed systems of systems (such as the digital twins of the Earth and the knowledge platforms) can manage the challenges posed by their evolutionary nature and create the necessary conditions to be sustainable and thrive. The ecosystem model encapsulates the need for the diversity of actors and expertise, focusing on synergies and relationships, and favoring the capacity to produce common outcomes for the benefit of Society – what ecologists call the ecosystem services – over time.

In the geosciences domain, digital ecosystems are called to enable the coevolution (i.e., the complex interplay between competitive and cooperative business strategies) of geosciences public and private organizations around the new opportunities and capacities offered by the digital transformation of society – Internet, big data, and computing virtualization processes represent some of the main engines of innovation, rising an entirely new type of geosciences ecosystems. A successful geosciences digital ecosystem enables the implementation of big data value chains by bringing together data owners, data analytics companies, skilled data professionals, cloud service providers, companies from the user industries, venture capitalists, entrepreneurs, research institutes, and universities. Geosciences digital ecosystems promote the necessary actions to allow these stakeholders to interact seamlessly within the digital market, leading to business opportunities, easier access to knowledge and resources (European Commission 2015). Three framework requirements are important to enable the formation and effective functioning of a digital ecosystem (Scott 2013):

1. The regulatory requirement – laws, policies, standards, and agreements that control the structure of the ecosystem components and their relations.
2. The institutional or organizational cultural requirement – the set of common social and cultural values that characterize the ecosystem. These values inevitably propel and restrain the behaviors of actors in the ecosystem.
3. The digital capabilities requirement – the key enabling technologies and interoperability services (e.g., computing, analytical, and communication services) that are utilized to introduce new actors (i.e., components) to the ecosystem.

Ecosystem Principles, Patterns, and Governance

To achieve an effective geospatial digital ecosystem, a typical implementation framework must consider a set of principles, development patterns, and governance styles (Nativi et al. 2021).

Evolvability and Resilience: A geosciences digital ecosystem operates in a highly dynamic environment in which technology, policies, and use needs are in constant evolution. Some of the recommended patterns are as follows:

- Implement a *High Flexibility and Modularity* level to decouple the enterprise digital systems (constituting the ecosystems) from the geosciences applications (e.g., digital twins) enabled by the ecosystem.
- Keep *Independence* from any specific provider, technology, or license – to secure industrial competitiveness and defend the value that the ecosystem may have at local/regional level, creating a social benefit.
- Preserve and facilitate the *Coevolution* of the ecosystem components, preserving their “diversity.” This increases the ecosystem resilience.
- Provide *Equal Opportunities* of access to the ecosystem and affordability for small organizations and across the digital value chain.
- Provide a *Metasystemic governance* of the ecosystem to govern its evolutions, adaptations, mutations, and strains.

Emergent Behavior (Maier 1998) of the Geosciences Digital Ecosystem As a Whole: For the enterprise systems belonging to an ecosystem, the aim is to create a value that is greater than (or different from) the value that they would have without being part of the ecosystem. Such utility can emerge autonomously, as the result of unpredictable interactions, or it can be planned, facilitated, and governed by an internal or external agent – e.g., normative and regulatory frameworks, and management intervention. To carefully plan and manage a geoscience digital ecosystem, it is useful to consider the following patterns (Nativi et al. 2021):

- *Belonging* versus *Autonomy*: A digital ecosystem is based on the paradox of autonomous and yet cooperative entities (DiMario et al. 2009). To belong to a digital ecosystem, an enterprise system must accept a certain level of reduction in its degree of autonomy and optimization, which can vary over time.
- *Common* versus *Enterprise value*: The emergence of a common ecosystem value must preserve (and hopefully reinforce) the utility of the contributing enterprise systems. This is achieved by allowing the enterprise systems to maintain a good degree of autonomy and diversity.
- *Critical mass*: A critical mass of services and users is needed to guarantee a return-of-investments and facilitate the ecosystem resilience.

- *Cost-effectiveness*: Duplication of efforts and resources must be avoided by: making use of shared components, leveraging economies of scale, and using standard and widely adopted technologies.

Enterprise Systems Dispersion: The enterprise systems, constituting a geoscience digital ecosystem, are generally disperse (i.e., geographically distributed and heterogeneous) and cope with big data. Therefore, the resulting ecosystem must deal with the challenges characterizing the “big data” cyber-physical realm and implement appropriate strategies to manage volume, velocity, variety, and value of data from multiple sources in a scalable way. To do that, presently, network computing is one of the most critical areas. Therefore, the digital ecosystem must optimize the nexus of four (often conflicting) minimization factors: data movement minimization, data replication minimization, analytics time lapse minimization, and energy consumption minimization, while preserving distributed data ownership. Useful patterns to be considered are:

- *Computing continuum* (osmotic computing): This paradigm introduces a holistic distributed system abstraction enabling the deployment of lightweight microservices on resource-constrained platforms at the network edge, coupled with more complex microservices running on large-scale datacenters (Baresi et al. 2019). Applications can choose to execute parts of their logic on different infrastructures that constitute the continuum (e.g., mobile, edge, fog, and cloud computing), with the goal of minimizing latency and energy consumption while maximizing availability.
- *Optimizing vs Satisficing design strategy* (Simon 1956): Ecosystem engineering is concerned more with satisficing performance (a decision-making strategy aiming at finding a satisfying and sufficing solution), rather than optimization of system performance. In a complex environment (like the geospatial digital ecosystem one) the optimization strategy can be too expensive and time-consuming and the simple selection of the first “good enough” option can result more rational – e.g., for real-time decision-making.

Effective governance: The success of a digital ecosystem largely depends on the appropriate governance of the ecosystem as a whole. The enterprise systems constituting a geospatial digital ecosystem are existing and autonomous structures, managed by different organizations. The governance of a geospatial digital ecosystem must define and apply the set of rules and principles that will help steer the ecosystem evolution and effectiveness through the many changes occurring at the political, social, cultural, scientific, and

technological environment where it operates. Different governance styles are possible (Holt et al. 2015; Nativi et al. 2021):

- *Virtual governance*: There is no central management authority and no centrally agreed-upon purpose for the ecosystem.
- *Acknowledged governance*: There is a central management organization without coercive power to run the ecosystem, but enterprise systems interact more or less voluntarily to fulfill agreed-upon central purposes.
- *Collaborative governance*: Like in the following *Directed* governance style, there are recognized objectives, a designated ecosystem manager, and specific resources allocated for the ecosystem. However, like in the previous *Acknowledged* case, the normal operational mode of the enterprise systems is not subordinated to the central managed purpose and they retain their independent ownership, objectives, funding, and development and sustainment approaches.
- *Directed governance*: An integrated ecosystem is built to fulfill specific purposes and is centrally managed to continue to fulfill those purposes, as well as any new ones the ecosystem owners might wish to address.

Some Significant Research and Innovation Aspects

Evolutionary Aspect

Geospatial digital ecosystems are subject to a constant pressure caused by internal changes (e.g., enterprise system evolutions, new system addition) as well as external ones (e.g., political, socioeconomic, and technological changes). These inevitable modifications request the ecosystem to continuously evolve. To avoid controlling those changes would result in being very disruptive for the provision of the ecosystem common utility services and, hence, hampering the survival of the ecosystem itself. Therefore, a geospatial digital ecosystem must be designed, managed, and operated as a highly dynamic system-of-systems (Nativi et al. 2021) as depicted in Fig. 1, where, in addition to the external pressure, internal changes are represented by the organizations #K and #N that evolves over time and decides to join the ecosystem, respectively. To allow a geospatial digital ecosystem resilience and evolution, the governance must define and manage the acceptable behaviors of enterprise systems, the acceptable boundary of their time evolutions (i.e., belonging versus autonomy levels boundary), and the consequent communication and interoperability instruments, which must be supported by the digital ecosystem, to acknowledge and control such changes.

Geosciences Digital Ecosystems, Fig. 1 The dynamic nature of geospatial digital ecosystems (Nativi et al. 2021)

Metasystemic Aspect

Being a dynamic supersystem, a geospatial digital ecosystem must detect changes and respond to them. In other words, a geospatial digital ecosystem must be implemented as a viable system, which recognizes as invariant the process of change, rather than the component or services that change (Turchin 1995). A digital ecosystem becomes a collection of parts that are dynamically related and such dynamicity must be carefully formalized and governed, through the development of efficient communication and control functions (cybernetic mechanism). To survive, therefore, a geospatial digital ecosystem must realize a metasystem transition (Turchin 1995). As showed in Fig. 2, the metasystem level stands “above” and “beyond” the controlled system-of-systems: i.e., the dynamic set of connected and transforming enterprise systems. The metasystem communicates through a governance language (a metalanguage) that is based on a set of invariable elements – i.e., principles, interoperability rules, technology patterns, common values, etc. With reference to Fig. 2, the main elements and their relationships are (Nativi et al. 2021):

- Metasystem schema – including the geospatial digital ecosystem invariants.
- Governance style and Cybernetic mechanisms – to apply the metasystem rules.
- System-of-systems architecture topology – largely depending from, and governed by the governance style, the cybernetic mechanisms, and the agreed digital ecosystem common utility.

Summary and Conclusions

In a digital society, the interconnection between the physical and the digital world has become almost complete. To monitor, understand, and simulate our planet behavior, public and private stakeholders can now interact in the “cyber-physical” world, in a more effective and intense way. This represents an important paradigm shift (in respect to the traditional data exchange approach), which requires a cultural, organizational, economic, and legal evolution.

Geosciences Digital Ecosystems, Fig. 2 The main elements implementing a viable geospatial digital ecosystem (Nativi et al. 2021)

On the other hand, the increasing exchange of information, occurring in the cyber-physical domain among a dynamic set of autonomous systems, escalates the interaction complexity and introduces the need to preserve the effectiveness of the overall system for the benefit of all the stakeholders. Natural ecosystems with their capability to solve complex and dynamic problems through evolution and self-organization provide an interesting paradigm to address the complexity in an ever-changing cyber-physical environment.

Geoscience digital ecosystems leverage such organizational model to assure the generation and sharing of environmental knowledge for the benefit of Society through collaboration and competition of autonomous systems. As in the case of natural ecosystems, geoscience digital ones are subject to internal and external disruptive changes that threaten its effectiveness in providing the ecosystem services required by Society. For this reason, geospatial digital ecosystems need a governance assuring curation and protection. Such a governance should include a metasystem level implementing the cybernetic functionalities of communication and control that assure the desired invariance of an ecosystem that lives in a highly dynamic environment.

Then, the ecosystem is free to evolve, while keeping constant its values, principle, and traits for the benefit of the community.

Today, geospatial digital ecosystems provide those scalable analytical and interpretation services that are required to develop advanced simulation and projection models, notably the Digital Twins of the Earth (Nativi and Craglia 2021).

Geostatistical Seismic Inversion

Leonardo Azevedo and Amílcar Soares
CERENA, DECivil, Instituto Superior Técnico, Universidade de Lisboa, Lisbon, Portugal

Definition

Subsurface rock properties models play a vital role in different geosciences fields such as hydrocarbon reservoir modeling and characterization, groundwater management, and mining resources and reserves evaluation. These models require the integration of all the available data, which often comprises direct and indirect measurements. These data sets comprise borehole and geophysical data. The main problem of the integration of these data in the typical forward models, joint estimation or simulation, is the large difference between their spatial support. Hence, integrating and predicting the spatial distribution of these properties from geophysical data requires solving a challenging inverse problem. In geophysical inverse problems, the model parameters – subsurface rock and elastic properties – are perturbed until the predicted geophysical data match the observed one. In geostatistical geophysical inversion methods, geostatistical simulation tools are used to perturb and update the model parameters

due to their ability to integrate data with different resolutions, to account for the geological patterns, and to assess spatial uncertainty of the predictions.

Geophysical Inversion

Geophysical survey methods are effective tools for imaging subsurface rock properties in different contexts, particularly in deeper and complex geological environments. In geosciences, seismic reflection surveys are widely used to model and characterize the subsurface properties due to the versatility of the method to image the subsurface at different depths with distinct levels of detail. Briefly, seismic data represent acoustic waves reflected at interfaces of geological media with different elastic properties. The observed geophysical data, $\mathbf{d}_{\text{obs}}$, are linked to the subsurface rock properties, $\mathbf{m}$ (e.g., porosity and fluid saturations) through a mathematical operator $\mathbf{F}$ (i.e., the forward model):

$$\mathbf{d}_{\text{obs}} = \mathbf{F}(\mathbf{m}) + \mathbf{e}, \quad (1)$$

where $\mathbf{e}$ represents measurement errors and approximations of the physical phenomena during data processing. In seismic inversion, $\mathbf{F}$ is commonly approximated with the convolutional model

$$\mathbf{A} = \mathbf{r} * \mathbf{w}, \quad (2)$$

where the recorded seismic amplitude ($\mathbf{A}$) represents the convolution of the reflection coefficients ($\mathbf{r}$) with a known wavelet ($\mathbf{w}$). The reflection coefficients depend on the subsurface elastic properties (i.e., rock density and P- and S-wave propagation velocities). The wavelet is a numerical representation of the seismic pulse generated at the source location.

In geophysical inversion, one knows the solution $\mathbf{d}_{\text{obs}}$ and aims to predict the model parameter ($\mathbf{m}$) that better matches $\mathbf{d}_{\text{obs}}$. This is a challenging inverse problem as $\mathbf{F}^{-1}$ is not well defined. Geophysical inverse problems are ill-posed and non-unique solution due to bandwidth and resolution limitations of the recorded data, physical assumptions, and measurement errors. Consequently, inverse solutions, retrieved by any of the many available inverse methodologies, always involve a certain degree of uncertainty that needs to be assessed during their interpretation (Tarantola 2005).

Seismic inversion may be solved under deterministic or stochastic frameworks (Bosch et al. 2010). Deterministic methods allow retrieving a single best-fit model that matches the observed data in the least squares sense. The predicted models are always a smooth representation of the subsurface, and the uncertainty assessment from deterministic inverse solutions is hardly suitable for highly nonlinear inverse problems. On the other hand, stochastic seismic inversion methods allow predicting multiple possible models of the subsurface,

allowing to assess the uncertainty of the predictions. The uncertainty is represented by the full posterior distribution of the model parameters, assuming a prior probability distribution and given a set of observed data. There are several alternative stochastic inversion methods, which might be divided in two main categories.

Bayesian linearized seismic inversion methods (e.g., Buland and Omre 2003, Grana and Della Rossa 2010) allow obtaining an analytical expression for the posterior distribution under Gaussian, or multi-Gaussian, assumptions about the prior distribution of the model properties and the error distribution present in the data and the linearization of the forward model. Due to these assumptions, the solution is mathematically tractable but lacks real exploration of the uncertainty space in lieu of exact prior information.

Alternatively, stochastic sampling and optimization methods, which require the spatial coupling of the subsurface property of interest, might be used to solve the seismic inversion problem. A comprehensive review about these seismic inversion methods can be found in Doyen (2007) and Bosch et al. (2010). Iterative geostatistical seismic inversion is a class of stochastic seismic inversion algorithms. Due to the ability to include direct observations and incorporate the spatial information about the expected continuity patterns, these inversion approaches use geostatistical methods, namely, stochastic sequential simulation and co-simulations. These are generally used to generate and update a set of models until a satisfactory match between observed and predicted seismic data is achieved (Azevedo and Soares 2017).

Depending on the observed data, the existing inversion methods might predict the spatial distribution of elastic properties such as acoustic and elastic impedances and density, P- and S-wave velocities or be inverted directly for rock properties like facies, porosity, fluid saturation, and mineral fraction. The former requires the integration of a rock physics models to link the rock with the elastic domains (Mavko et al. 2003).

Trace-by-Trace Geostatistical Seismic Inversion

Bortoli et al. (1993) introduced the pioneering work on geostatistical seismic inversion proposing a sequential trace-by-trace approach to invert fullstack seismic for acoustic impedance. Each seismic trace (i.e., a vertical column of grid cells within the inversion grid) is visited individually following the framework of a stochastic sequential simulation. At each step along a predefined random path, N_s realizations of acoustic impedance are simulated using sequential Gaussian simulation (Deutsch and Journel 1998) taking the well-log data and previously visited/simulated traces into account. For each simulated impedance trace, the corresponding reflection coefficient is computed and convolved with a wavelet. This step results in a set of N_s synthetic seismic traces. Each synthetic trace is compared against the

observed seismic trace for the same location given an objective function such as the Pearson's correlation coefficient. The acoustic impedance realization that produces the lowest mismatch between the real and the synthetic seismic traces is integrated in the inversion grid as conditioning data for the simulation of the next location following the predefined random path. Different runs produce variable inverted models as the random path changes and, consequently, modify the conditioning data at each trace location. The variability among a set of inverted models allows the assessment of the spatial uncertainty related with the property of interest.

One of the main drawbacks of trace-by-trace stochastic seismic inversion methodologies is related to those areas of low signal-to-noise ratio. In areas of poor seismic signal, the sequential trace-by-trace approaches impose inverted models that fit the observed noisy seismic reflection data. As the simulated trace is assumed as true data for the next steps, this can lead to the spread of the noisy values.

Global Geostatistical Seismic Inversion

Global iterative geostatistical seismic inversion methods differ from the trace-by-trace approaches since the inversion grid is simulated at once for all the locations (Soares et al. 2007). This family of methods is based on two main ideas common to the different available methods. Direct sequential simulation and co-simulation are the preferable methods to generate sets of models at each iteration. The convergence of the iterative procedure to a known solution is assured with an optimization method based on a genetic algorithm. The elastic traces that at a given iteration ensure synthetic seismic traces with the highest similarity against the observed one are selected as conditioning data (i.e., secondary information) in the generation of a new set of models in the subsequent iteration. Figure 1 summarizes the main steps of global geostatistical seismic inversion.

In geostatistical elastic inversion, the first iteration starts with the simulation of a set of N_s models of the elastic properties of interest given the existing well-log data and a given spatial pattern as revealed by a variogram or spatial covariance model. A variogram model is a mathematical tool that describes the expected spatial continuity pattern of the property in study. Each simulated realization, by reproducing the variogram model, ensures the same spatial continuity pattern of the main properties. These realizations are then forward modeled to generate synthetic data. Depending on the observed data, the forward model might comprise the calculation of the normal incidence or angle-dependent reflection coefficients, which are then convolved with a wavelet (Eq. 1). Synthetic and real seismic traces are compared taking into account the waveform and amplitude content of the signal. Various equations might be used. Here we show a single equation that is sensitive to both parameters:

Geostatistical Seismic Inversion, Fig. 1 Schematic representation of the general workflow used in global iterative geostatistical seismic inversion methods

$$S = \frac{2 \sum_{k=-n}^n (d_{t+k} d_{t+k}^*)}{\sum_{k=-n}^n (d_{t+k})^2 + \sum_{k=-n}^n (d_{t+k}^*)^2}, \quad (3)$$

where d_t and d_t^* are the observed and predicted seismic traces at sample t and n is the size of a moving window used to compute the similarity between both traces. As in a correlation coefficient S varies between -1 and 1 , for implementation purposes, the negative values are truncated at zero. The elastic traces that produce the highest S at a given iteration are stored along with the similarity value in two auxiliary volumes. These volumes will be used as secondary variables in the stochastic sequential co-simulation of a new set of models in the following iterations. Regions of the inversion grid where S is high will exhibit a similar spatial pattern as the auxiliary elastic volumes. On the contrary, in regions where S is small, the auxiliary volume will have low impact. In other words, S controls the degree of assimilation of the observed data in the generation of elastic models in the next iteration. The iterative procedure is over when a given number of predefined iteration is reached or when the global similarity between observed and predicted data is above a user-defined threshold.

Once the convergence is reached, all the co-simulated models in the last iteration produce synthetic seismic highly similar to the observed one. Areas of poor signal-to-noise ratio in the observed data or areas where the wavelet is not representative of the recorded seismic tend to remain

unmatched during the entire iterative procedure and represent areas of high uncertainty. This ensemble of models might be used to assess the spatial uncertainty of the predictions by computing, for example, the pointwise variance or the inter-quantile distance.

All the simulated and co-simulated models share some common characteristics. They reproduce exactly the well-log data at the well locations, the marginal and joint distribution of the properties of interest, and the spatial continuity patterns as revealed by the variogram models. Also, depending on the variogram model used during the model simulation, the inverted models show higher resolution than the recording seismic, allowing to characterize layer at and below the seismic resolution.

Geostatistical seismic inversion has been developed to invert fullstack seismic for acoustic impedance, partial angle stacks for acoustic (Fig. 2) and elastic impedances, and partial angle stacks and angle gathers for density P-wave and S-wave velocities. As the goal of a geoscientist is to model the subsurface rock properties, the inverted elastic models are often used as starting point for this step of the geo-modeling workflow. However, the derived rock properties are not directly linked to the observed geophysical data, which might result in non-plausible subsurface models.

Recently, geostatistical seismic inversion methods have been extended to predict rock properties such as porosity, fluid, mineral fractions, and facies directly from the seismic data (Azevedo et al. 2017). In these methods, the iterative procedure generates the rock properties through geostatistical

Geostatistical Seismic Inversion, Fig. 2 Vertical well sections extracted from: (left and middle) two realizations of I_p generated during the last iteration of the geostatistical seismic inversion and the pointwise average model of all the realizations generated during the last iteration

Geostatistical Seismic Inversion, Fig. 3 Vertical well sections extracted from the pointwise average model of all the realizations generated during the last iteration for volume of shale (Vshale), porosity, facies, and water saturation

simulation. The simulated rock models are then converted into elastic properties using a calibrated rock physics model (Mavko et al. 2003). A rock physics model is a set of mathematical equations that links the subsurface rock properties to their corresponding elastic response. Rock physics models differ in terms of assumptions and complexities of the physical and mathematical formulation. A simple rock physics model might include simple empirical relations inferred from laboratory experiments or be more complex and based on the Hertz-Mindlin contact theory or inclusion theory. A detailed description of rock physics models and workflows is available in Mavko et al. (2003). Contrary to geostatistical elastic inversion, in these methods, the predicted subsurface rock properties are directly linked to observed seismic data (Fig. 3).

Summary

Iterative geostatistical geophysical inversion is versatile methods to predict subsurface rock properties from

geophysical data. These techniques have had a significant evolution both in terms of applications and in new methodological approaches. New field of applications, like geotechnical characterization of the near-surface and for groundwater management, are using geostatistical geophysical inversion for better characterizing the spatial patterns of geomechanical and geotechnical properties of the subsurface.

As for the new methodological approaches, with the generalization of spatial data science methods, these can be integrated in the geostatistical seismic inversion workflow with two complementary objectives. For example, deep learning methods like generative adversarial networks are promising techniques to model categorical variables such as facies, and its inclusion in geophysical inversion might open the door to the integration of greater geological information content in the inversion procedure and be used to falsify unreliable geological scenarios.

In addition, a new generation of the self-learning methods has been developed to tune and optimize the inversion meta-parameters as defined by the local variogram parameters (i.e., the local variogram dip, azimuth, and ranges) and the

marginal and joint distributions of the inverted properties. Briefly, the data mismatch is used not only for the selection of the best elastic or rock property traces at the end of each iteration but also to update the meta-parameters using a self-learning approach.

Geostatistics

H. S. Pandalai¹ and A. Subramanyam²

¹Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India

²Department of Mathematics, Indian Institute of Technology Bombay, Mumbai, India

Definition

Geostatistics is the collection of techniques that deals with spatio-temporal phenomena using data assumed to be realizations of a collection of random variables generated via a random process. Typically, the data are such that the joint probability distributions of this random process cannot be

readily modeled. The geostatistical approach is characterized by modeling the random process by making appropriate hypotheses that permit estimation of second-order or higher moments of bivariate and multivariate distributions of the random variables. The two broad problems addressed by geostatistics are those of prediction and simulation of random variables on different supports, and their functions.

Introduction

Understanding natural phenomena often requires models to be built based on observations. A large part of comprehending and characterizing natural phenomena is achieved by making numerical observations on them. Mathematical models are made from such numerical observations. The subject of mathematical geosciences concerns the study of mathematical models developed for the geosciences. Often, numerical observations on natural phenomena have an element of randomness in them owing to the intrinsic nature of the phenomenon and due to random errors involved in making the observations. Statistical methods are used to make appropriate models that take into account such randomness. Statistical techniques such as inference, design of experiments, multiple regression, categorical data analysis, and other multivariate techniques are used in all branches of scientific enquiry, including the Earth Sciences. The term *Geostatistics* is, however, used for a collection of statistical techniques originally developed to address questions that arose in the mining industry, and later came to have much wider applications in several branches of scientific study. For example, a volume V (called a “panel”) which is a designated part of a mineral deposit is to be mined out. The volume V is generally mined out in smaller portions (called “blocks”) of volume v . The contents of such blocks are sent for extraction to a mill or to a waste dump depending upon whether their average grades exceed a threshold determined by economic parameters. Questions such as (i) what is the average grade of the panel, (ii) what proportion of blocks in a panel can be sent to the mill for extraction, or (iii) what is the average grade of material from panels that are sent to the mill, are of interest in the mining industry. Similar questions also arise in other fields of study such as in petroleum reservoir studies, agriculture, forestry, fisheries, and environmental studies, to name a few.

A feature that distinguishes geostatistics from many other statistical techniques is that it deals with the modeling of spatial phenomena with the aim of capturing the nature of their essential randomness as well as their inherent spatial structure. Thus, geostatistics is an aspect of the general theory of stochastic processes which deals with the study of collections of random variables. The general study of stochastic processes includes the study of time-series, Markov processes, diffusion processes, point processes, and others besides geostatistics.

Geostatistics had its origins in the observations of Daniel G. Krige in 1951 and 1952 that the grades of a panel estimated by the average grades of observed values in core-samples in and around the panel was often biased. In particular, panels estimated as having high grade often actually produced lower grade of ore when mined out. He sought to remedy this by assigning weights to the observations depending upon whether they were inside or outside the panels based on regression of the average grade of these groups of samples using historical mining data. Georges Matheron who had come across similar problems worked on a mathematical formulation for solving the problem and developed a more general method for assigning weights to observed data in the process of estimation. Matheron (1960, 1963) called this more generalized approach “kriging” (or “krigeage” in French) in honour of Daniel Krige.

The basis of the original technique developed by Matheron is a certain set of assumptions (called second-order stationarity) that will be discussed later in detail. Since the introduction of “kriging” in this form, it has been further generalized and modified to suit several other situations involving various other assumptions. These techniques involve the modeling of stochastic processes under various constraints.

The problem of “change of support” is a problem that was first identified in geostatistics and arose initially in applications concerning the mining industry. For example, when grades of core-samples are the observations available and it is desired to obtain estimates of functions of average grades defined over volumes different from that of the core-samples. Defining the relationship between the average grade of a panel of volume V with the help of core-samples of volume v constitutes a unique problem in the realm of stochastic processes. This problem is called the “problem of change of support” and is a contribution of geostatistics to the study and modeling of stochastic processes.

Another significant line of work in geostatistics has been that of developing techniques for generating multiple realizations of a stochastic process with a given characteristic – a technique known as simulation. With the increasing availability of superior computing power, great advances have been made in the simulation of stochastic processes, providing solutions to many problems addressed by geostatistics.

Statistical Formulation

The statistical approach to data analysis is to assume that observations are realizations of random variables (RV s). Let x be a point in D , the region of study, and let $s(x)$ be a small volume centered at x . Usually the volume $s(x)$ is constant for all x . The average value over $s(x)$ of the characteristic of interest is attributed to the point x and denoted by $z(x)$. The

approach to probabilistic analysis is to consider that $z(x)$ observed at each x is the realization of an RV , $Z(x)$. This leads to a collection of RV s, $\{Z(x), x \in D\}$. Such a collection of RV s is known variously in literature as *stochastic process*, *random process*, *random field*, *random function*, etc. In geostatistics the term random function is used more commonly. In the sequel these terms are used interchangeably. The collection $\{z(x), x \in D\}$ of realizations of RV s or a realization of the random function $\{Z(x), x \in D\}$ is called a *regionalization*. The region of study D can be multi-dimensional. In particular it could be a subset of three-dimensional space thereby bringing in spatial aspects into the analysis. In other examples D could also include a dimension of time, in which case the analysis would be spatio-temporal.

In many applications of geostatistics, the average value $z_V(x)$ of the characteristic of interest over a volume V centered at location x is desired. Mathematically, $z_V(x)$ is given by $\frac{1}{|V|} \int_{V(x)} z(u) du$. This value $z_V(x)$ is the realization of the random variable $Z_V(x)$. The problem in geostatistics is often that of predicting the value of $z_V(x)$ given $z(x_1), z(x_2), \dots, z(x_N)$ which are observations at N locations in and around V . This problem can be solved using standard statistical techniques provided the joint distribution of the RV s, $(Z_V(x), Z(x_1), Z(x_2), \dots, Z(x_N))$, is known. When this joint distribution is known, the conditional expectation, $E[Z_V(x) | Z(x_1), Z(x_2), \dots, Z(x_N)]$ is the function that minimizes the expected value of the squared error of prediction among all estimators of the type $g(Z(x_1), Z(x_2), \dots, Z(x_N))$, provided all the RV s have finite variance. This is the case, for example, if the random process is assumed to be Gaussian wherein the joint distributions can be shown to be multi-Gaussian.

In the sequel the random process (or random function) $\{Z(x), x \in D\}$ is abbreviated as Z . Probabilistically, the random function is completely specified only when all finite-dimensional joint distributions of collections of the type $\{Z(x_1), Z(x_2), \dots, Z(x_K)\}$ for $x_i \in D, i = 1, 2, \dots, K$ and for all $K = 1, 2, 3, \dots$ (termed, in geostatistics as the spatial law of the random function) are specified. This is the case when the random process is Gaussian. Unfortunately, it is most often not possible to specify the spatial law of random functions.

In practice, data is often only adequate to model the marginal distribution of $Z(x)$ under the assumption that all $\{Z(x), x \in D\}$ are identically distributed. To solve problems that arise in geostatistics, such as prediction problems, it is necessary to make reasonable assumptions on the random process Z that enable moments of higher order to be estimated from the data. In the study of stochastic processes, assumptions collectively termed “assumptions of stationarity” make probabilistic analysis mathematically tractable and form the basis of the mathematical model (Cressie 1991).

Stationarity

The assumptions of stationarity impose certain levels of homogeneity in the random process. A most stringent assumption on Z would be to assume that the joint distribution of $\{Z(x_1), Z(x_2), \dots, Z(x_N)\}$ is the same as that of $\{Z(x_1 + \vec{h}), Z(x_2 + \vec{h}), \dots, Z(x_N + \vec{h})\}$ for all $\vec{h}$ and all N such that $x_i, x_i + \vec{h} \in D$, $i = 1, 2, \dots, N$. This assumption on Z is termed *strict stationarity*. Essentially this means that the joint distribution of $\{Z(x_1), Z(x_2), \dots, Z(x_N)\}$ is invariant under translation. A weaker assumption would be to require that this assumption is true for $N = 2$ and every fixed $\vec{h}$ (i.e., *bivariate stationarity*). In other words, under this hypothesis it is assumed that all pairs of random variables $\{Z(x_1), Z(x_2)\}$ have the same distribution as $\{Z(x_1 + \vec{h}), Z(x_2 + \vec{h})\}$ and this is true for any pair x_1, x_2 such that $\{x_1, x_2\}$ and $\{x_1 + \vec{h}, x_2 + \vec{h}\} \in D$. Equivalently, pairs $\{Z(x), Z(x + \vec{h})\}$ have the same distribution for all x , $x + \vec{h} \in D$. A further weakening of bivariate stationarity is achieved by requiring that only the first and second moments of pairs $\{Z(x), Z(x + \vec{h})\}$ are the same for all x . This assumption is called the assumption of *second-order stationarity*. Under second-order stationarity, the following are true:

- (i) $E[Z(x)] = m \quad \forall x$
- (ii) $Var[Z(x)] = E[Z(x) - m] = \sigma^2 \quad \forall x$
- (iii) $Cov[Z(x), Z(x + \vec{h})] = E[(Z(x) - m)(Z(x + \vec{h}) - m)]$
 $= C(\vec{h}) \quad \forall x$

Second-order stationarity implies $\frac{1}{2}E[(Z(x) - Z(x + \vec{h}))^2] = \gamma(\vec{h}) \quad \forall x$ where $\gamma(\vec{h})$ is called the *semivariogram*. Clearly $C(0) = \sigma^2$ and $\gamma(\vec{h}) = C(0) - C(\vec{h})$ under second-order stationarity.

It is interesting to note that there exist processes in which $\gamma(\vec{h})$ exists but $C(\vec{h})$ does not. Obviously, such processes are not second-order stationary. Matheron (1973) termed such random functions as *intrinsic random functions of order 0*. In such processes, mean and the variance of differences exist (i.e., $E[Z(x)] = m \quad \forall x$, and $Var(Z(x) - Z(x + \vec{h})) = E[(Z(x) - Z(x + \vec{h}))^2] = 2\gamma(\vec{h}) \quad \forall x$).

The assumptions of stationarity cannot be expected to be valid over a large region. Hence, in practice, often sliding neighborhoods in which stationarity is assumed are considered. This assumption is termed *quasi-stationarity* (Journel and Huijbregts 1978). When there is only a single realization of the random function, the assumptions of stationarity cannot be verified and it remains a mathematical model (Myers 1989).

Properties of the Covariance and Variogram Functions

By considering the nonnegative quantity variance of a linear combination of *RVs*, $Var\left(\sum_{i=1}^n \lambda_i Z(x_i)\right) = \sum_{i=1}^n \lambda_i^2 \sigma^2 + 2 \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C(x_i - x_j) \geq 0$, it follows that the $n \times n$ matrix whose ij^{th} element is given by $C_{ij}(x_i - x_j)$ is nonnegative definite. Therefore, the covariance function $C(\vec{h})$ of every second-order stationary random function is a positive definite function. In the case of second-order stationary random functions, it can be seen that $\sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C(x_i - x_j)$ can be written as $\left(C(0) \sum_{i=1}^n \lambda_i \sum_{j=1}^n \lambda_j - \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \gamma(x_i - x_j)\right) \geq 0$. When $\sum_{i=1}^n \lambda_i = 0$, $-\sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \gamma(x_i - x_j) \geq 0$. Such a function $\gamma(h)$ is called a *conditionally negative definite function*. The variogram of every second-order stationary random function should therefore be a conditionally definite function.

Other important properties of the covariance of a second-order stationary random function are (i) $C(0) \geq C(\vec{h})$, (ii) $C(\vec{h}) = -C(-\vec{h})$. For the semivariogram function, (i) $\gamma(0) = 0$ and (ii) $\gamma(\vec{h}) = \gamma(-\vec{h})$. If $C(\vec{h}) = 0$, or equivalently $\gamma(\vec{h}) = \text{constant}$ for $\|\vec{h}\| > r$, then the smallest value of r for which this occurs is called the *range* of the semivariogram or covariance function and the value of the constant is called the *sill* of the semivariogram. When this occurs the random function Z is said to be *transitive*.

Nonstationary Random Functions and the Generalized Covariance Function

It is not always possible to assume that $m(x)$, the mean of $Z(x)$, is a constant at all locations x . In many natural situations it is more realistic and appropriate to assume that $Z(x) = Y(x) + m(x)$, where $Y(x)$ has zero mean and $m(x)$ is a deterministic (non-random) function of x that is commonly called “*drift*.” It may be postulated that $m(x) = \sum_{l=0}^L a^l f^l(x)$, where $f^0, f^1, \dots, f^L$ are some known basis functions. Since the function $m(x)$ is unknown, the coefficients $a^0, a^1, a^2, \dots, a^L$ are also unknown. It is, however, possible to solve equations of the type $\sum_{\alpha=0}^n w_\alpha f^l(x_\alpha) = 0, \quad l = 0, 1, \dots, L$ under the condition that $w_0 = -1$ (i.e., $\sum_{\alpha=1}^n w_\alpha f^l(x_\alpha) = f^l(x_0), \quad l = 0, 1, \dots, L$). The weights w_α are said to filter the basis functions. For such weights, $w_\alpha, \alpha = 0, 1, \dots, n$, $\sum_{\alpha=0}^n w_\alpha Z(x_\alpha)$ has zero mean even though the a^l s are unknown. If it is assumed that $m(x)$ is a polynomial, then the f^l s can be taken as appropriate

monomials. For example in $\mathfrak{R}^2$, $x \equiv (x_1, x_2)$ and $f^0(x) = 1$, $f^1(x) = x_1$, $f^2(x) = x_2$, $f^3(x) = x_1^2$, $f^4(x) = x_2^2$ and $f^5(x) = x_1 x_2$.

If the process $Z_W(s) = \left\{ \sum_{\alpha=0}^n w_\alpha Z(x_\alpha + s), \forall s \in D \right\}$ is a second-order stationary process for every set of weights w_α that satisfy $\sum_{\alpha=0}^n w_\alpha f^l(x_\alpha) = 0$, $l = 0, 1, \dots, L$, then the process $Z = \{Z(x), x \in D\}$ is said to be an *intrinsic random function* and the linear combination $\sum_{\alpha=0}^n w_\alpha Z(x_\alpha)$ is said to be an *authorized linear combination*. The choice of basis functions is restricted by the requirement that $\sum_{\alpha=0}^n w_\alpha Z(x_\alpha + s)$ is an authorized linear combination for all s . In other words, the weights w_α should ensure that $\sum_{\alpha=0}^n w_\alpha f^l(x_\alpha + s) = 0$, $\forall s$ and $l = 0, 1, \dots, L$ thereby filtering the basis functions evaluated at $x_\alpha + s$, $\alpha = 0, 1, \dots, n$, $\forall s$. Owing to convenience it is customary to use polynomials, although other functions such as exponential and trigonometric functions meet the requirement. An intrinsic random function $Z = \{Z(x), x \in D\}$ with a polynomial drift of order k is said to be an *intrinsic random function of order k , (IRF - k)*.

Consider a process $Z = \{Z(x), x \in D\}$ with $Z(x) = Y(x) + m(x)$, where $E[Y(x)] = 0$ and $m(x)$ is a polynomial of order k . Assume that $m(x) = \sum_{l=0}^L a^l f^l(x)$. If $m(x) = 0 \quad \forall x$, (or is a known constant) and $Y = \{Y(x), x \in D\}$ is a second-order stationary process. Then the process Z is stationary and is said to be an *intrinsic random function of order (-1)* (i.e., an *IRF(-1)*). An *IRF(-1)* process is identical to a second-order stationary random process. If $m(x)$ is an unknown constant $\forall x$, then $m(x) = a^0 f^0(x)$ where $f^0(x) = 1$. So $\sum_{\alpha=0}^n w_\alpha f^0(x_\alpha) = 0$ implies $\sum_{\alpha=1}^n w_\alpha = 1$. Such a process Z is said to be an *IRF - 0* and is identical to a process that has the property of intrinsic stationarity. For example, when $n = 1$, $w_0 = -1$ and $w_1 = 1$ and an authorized linear combination is the difference $(Z(x_\alpha) - Z(x_0))$. Such differences are also called “increments.”

Consider now an *IRF - k* process Z and an authorized linear combination $Z_W(s) = \sum_{\alpha=0}^n w_\alpha Z(x_\alpha + s)$. Clearly, $E[Z_W(s)] = 0 \quad \forall s$ and $Var[Z_W(s)] = V_W$, say, $\forall s$. It can be shown that the covariance of the *IRF - k* process Z can be written as $Cov[Z(x), Z(y)] = C_Z(x, y) = K(x - y) + \sum_{l=0}^L c^l(x) f^l(y) + \sum_{l=0}^L c^l(y) f^l(x)$ where $K(\vec{h})$ is a function, $c^l s$ are appropriate constants, and $f^l s$ are monomials (Delfiner 1982). The variance of an authorized linear combination can be written as $E[Z_W(s)]^2 = \sum_{\alpha=0}^n \sum_{\beta=0}^n w_\alpha w_\beta K(x_\alpha - x_\beta) = V_W \geq 0$ for a function K . This function $K(\vec{h})$ is called the

generalized covariance function of the random process Z (Chiles and Delfiner 2012). A property of this function is that it is symmetric and conditionally positive definite (i.e., positive definite conditional to $Z_W(s)$ being an authorized linear combination). For example, for an *IRF - 0* process, the function $K(\vec{h}) = -\gamma(\vec{h})$ which is conditionally positive definite since $\gamma(\vec{h})$ is known to be conditionally negative definite.

When the random process Z is written as $Z(x) = Y(x) + m(x)$ with $E[Y(x)] = 0$, the process $Y(x)$ may or may not be second-order stationary. It can be seen that

$$Cov[Z(x), Z(y)] = C_Z(x, y) = E[(Z(x) - m(x))(Z(y) - m(y))] = Cov[Y(x), Y(y)] = C_Y(x, y), \text{ say} \quad \text{and} \\ \frac{1}{2} Var[Z(x) - Z(y)] = \gamma_Z(x, y) = \frac{1}{2} E[(Z(x) - Z(y)) - (m(x) - m(y))]^2 = \frac{1}{2} Var[Y(x) - Y(y)] = \gamma_Y(x, y), \text{ say}.$$

In general $C_Y(x, y)$ and $\gamma_Y(x, y)$ (and therefore $C_Z(x, y)$ and $\gamma_Z(x, y)$) are inaccessible, but in some situations where appropriate models can be inferred, these covariance functions and semivariograms can be used for predictions of Z under appropriate unbiasedness conditions. In working with an *IRF - k* process Z , one may use its covariance function $C_Z(x, y)$ if it is known or can be modeled. In all other situations one has to resort to working with authorized linear combinations $Z_W(s) = \sum_{\alpha=0}^n w_\alpha Z(x_\alpha + s)$ and the generalized covariance of Z . In general, to determine the appropriateness of an *IRF - k* model in a given situation and the estimation of the generalized covariance are difficult problems. Some iterative methods for evaluation of the order k of the drift and estimation of the generalized covariance are given in Delfiner (1982) and Chiles and Delfiner (2012).

Coregionalization

In many situations, at any given location, more than a single characteristic of a phenomenon may be manifested. For example, a core-sample of mineralized rock could contain a set of elements of interest. In such cases, at each location the observations consist of a vector $\mathbf{z}(x) = (z_1(x), z_2(x), \dots, z_p(x))^T$. The vector $\mathbf{z}(x)$ is considered as the realization of a random vector $\mathbf{Z}(x)$. Consequently, the expected value $E[\mathbf{Z}(x)] = \boldsymbol{\mu}(x)$ is a p -dimensional vector. The dispersion of the random vector is described by its covariance matrix $\boldsymbol{\Sigma}(x)$ which is a $p \times p$ matrix whose ij^{th} element is given by $Cov(Z_i(x), Z_j(x)) = E[(Z_i(x) - \mu_i(x))(Z_j(x) - \mu_j(x))]$. The random process $\mathbf{Z} = \{\mathbf{Z}(x), x \in D\}$ is similarly defined as in the case where $p = 1$. In particular, second-order stationarity would imply:

- (i) $E[\mathbf{Z}(x)] = \boldsymbol{\mu} \quad \forall x$
- (ii) $Var[\mathbf{Z}(x)] = \boldsymbol{\Sigma} \quad \forall x$
- (iii) $Cov[\mathbf{Z}(x), \mathbf{Z}(x + \vec{h})] = \boldsymbol{\Sigma}(\vec{h}) \quad \forall x$

where, $\Sigma(h)$ is a $p \times p$ matrix whose ij^{th} element is given by $Cov(Z_i(x), Z_j(x+h)) = C_{ij}(h)$. The term auto-covariance is used for the function $C_{ii}(h)$ and the term cross-covariance for $C_{ij}(h)$ when $i \neq j$. It is important to observe here that the matrix $\Sigma(h)$ is not symmetric, that is, it is not necessary that $C_{ij}(h) = C_{ji}(h)$.

The semivariogram matrix $\Gamma(\vec{h})$ is defined here as $\frac{1}{2}E[(\mathbf{Z}(x) - \mathbf{Z}(x+\vec{h}))(\mathbf{Z}(x) - \mathbf{Z}(x+\vec{h}))^T]$. The ij^{th} entry in $\Gamma(\vec{h})$ is given by $\frac{1}{2}E[(Z_i(x) - Z_i(x+\vec{h}))(Z_j(x) - Z_j(x+\vec{h}))]$. The matrix $\Gamma(\vec{h})$ is symmetric and may exist even when $\Sigma(\vec{h})$ may not.

It is difficult to characterize the covariance matrix $\Sigma(\vec{h})$, although it can be done in terms of spectral distributions and spectral densities as a generalization of Bochner's Theorem (see, e.g., Chiles and Delfiner 2012, and related references therein). However, for practical situations, the following models are useful: (i) $\Sigma(\vec{h}) = \mathbf{B} C(\vec{h})$ where $C(\vec{h})$ is the covariance function of a univariate random function (i.e., a positive definite function) and $\mathbf{B}$ is a positive definite matrix, and (ii) If $C_1(\vec{h}), C_2(\vec{h}), \dots, C_k(\vec{h})$ are positive definite functions and $\mathbf{B}_1, \mathbf{B}_2, \dots, \mathbf{B}_k$ are positive definite matrices, then $\sum_{i=1}^k \mathbf{B}_i C_i(\vec{h})$ is a valid matrix covariance function (Wackernagel 2003). Similarly, valid matrix semivariogram functions $\Gamma(\vec{h}) = \mathbf{B} \gamma(\vec{h})$ and $\Gamma(\vec{h}) = \sum_{i=1}^k \mathbf{B}_i \gamma_i(\vec{h})$ can be obtained where $\gamma(\vec{h})$ and $\gamma_i(\vec{h})$ are valid semivariograms and $\mathbf{B}$ and $\mathbf{B}_i$ are positive definite matrices. When the covariance matrix $\Sigma(\vec{h})$ is modeled as in (i) above, it is postulated that random functions $Z_1, Z_2, \dots, Z_p$ that are elements of the random vector $\mathbf{Z}$ are fundamentally related to a single underlying generating process whose covariance and semivariogram are characterized by $C(\vec{h})$ and $\gamma(\vec{h})$, respectively, and $\mathbf{Z}$ is said to be *intrinsically coregionalized*. If on the other hand, $\Sigma(\vec{h})$ is modeled as in (ii) above, the random vector $\mathbf{Z}$ is considered as the weighted sum of k independent random vectors $\mathbf{W}_1, \mathbf{W}_2, \dots, \mathbf{W}_k$, with covariance matrices $\Gamma_1(\vec{h}), \Gamma_2(\vec{h}), \dots, \Gamma_k(\vec{h})$, respectively, wherein each random vector $\mathbf{W}_i$, $i = 1, 2, \dots, k$ is modeled as in (i) above. In such a case, the random vector $\mathbf{Z}$ is said to admit the *linear model of coregionalization (LMC)*.

In applications, it is often of interest to study functions $\mathbf{Y}(x) = g(\mathbf{Z}(x))$. In such situations, a new process $\mathbf{Y} = \{\mathbf{Y}(x), x \in D\}$ is considered. The matrix covariance and semivariogram functions are denoted by $\Sigma_Y(\vec{h})$ and $\Gamma_Y(\vec{h})$, respectively. Often the function g of interest is the indicator function $\mathbf{Y}(x) = \mathbf{I}_{\mathbf{Z}(x) \in A}(x)$ where A is a set in $\mathfrak{R}^p$. When $p = 1$, $Y(x) = I_{Z(x) \in A}(x)$ where A is some set in $\mathfrak{R}$ and correspondingly the covariance and semivariogram functions

of $Y(x)$ are termed *indicator covariance* and *indicator semivariogram*, respectively. In the general case the ij^{th} elements of $\Sigma_Y(\vec{h})$ and $\Gamma_Y(\vec{h})$ are given by $C_{Y_i Y_j}(\vec{h})$ and $\gamma_{Y_i Y_j}(\vec{h})$ which are the cross-indicator covariance and cross-indicator semivariogram, respectively.

Estimating Covariance and Variogram Functions

When using models of $\mathbf{Z}$ that are specified in terms of $\Sigma(h)$ or $\Gamma(h)$, these matrix functions are to be estimated from observed data. This involves the estimation of auto- and cross-covariance and semivariogram functions, that is, $C_{ij}(h)$ and $\gamma_{ij}(h)$, respectively.

Data Configurations

In applications of geostatistics, the p -dimensional random process $\mathbf{Z} = \{\mathbf{Z}(x), x \in D\}$, may be observed at locations, x_α , $\alpha = 1, 2, \dots, N$. In many applications, all p elements of the random vector $\mathbf{Z}(x)$ may not be observed at all locations. The most general data configuration is that at each x_α at least one of the components of the random vector $\mathbf{Z}(x)$ is observed. Data configurations can broadly be classified into *isotopic* and *heterotopic*. A data configuration is said to be isotopic if all the p -components of $\mathbf{Z}(x)$ are observed at all N data locations; otherwise, the data configuration is said to be heterotopic. In the case where $p = 1$, the data configuration would be isotopic. When the data configuration is heterotopic, it is said to be *completely heterotopic* (or *dislocated*) if no two components of the random vector $\mathbf{Z}(x)$ are observed at the same location. Heterotopic data in which more than one component of $\mathbf{Z}(x)$ is observed at some locations is said to be *partially heterotopic*.

In applications, it may be of interest to predict some of the components of $\mathbf{Z}(x)$ at location x_0 where these components are unobserved. In such situations, the component that is to be estimated is said to be the *primary variable* while the other components are said to be secondary or *auxiliary variables*. Auxiliary variables may or may not be observed at the location x_0 where the primary variable is to be predicted. When auxiliary variables are available at the location where prediction is required, the data configuration is said to be *collocated*. Further, if the auxiliary variables are observed only at the location x_0 where prediction is desired and nowhere else (or if auxiliary variables elsewhere except at x_0 are ignored for the purpose of prediction), the data configuration is said to be *strictly collocated*. The term *multicollocated* is used to describe the situation where auxiliary variables are observed at all locations where the primary variable is observed and additionally at the location x_0 where prediction of the primary variable is to be made.

Modeling Experimental Covariances and Semivariograms

The estimation of auto-covariances and semivariograms is considered first and for this purpose, without loss of generality, p is taken to be equal to 1. The observed data $z(x_1), z(x_2), \dots, z(x_N)$ are the realizations of $Z(x_1), Z(x_2), \dots, Z(x_N)$. Under second-order stationarity (or intrinsic stationarity) $E[Z(x)]$ is estimated by $\frac{1}{N} \sum_{i=1}^N z(x_i) = m$, say. Clearly all pairs $(z(x_i), z(x_j))$ with $(x_i - x_j) = \vec{h}$ can be used to estimate $C(\vec{h})$ and $\gamma(\vec{h})$. The estimators $\hat{C}(\vec{h})$ and $\hat{\gamma}(\vec{h})$ called the *experimental covariance* and *experimental semivariogram*, respectively, are given by $\hat{C}(\vec{h}) = \frac{1}{n} \left(\sum_{i=1}^n z(x_i) z(x_i + \vec{h}) - m^2 \right)$ and $\hat{\gamma}(\vec{h}) = \frac{1}{2n} \sum_{i=1}^n \left(z(x_i) - z(x_i + \vec{h}) \right)^2$, where n is the number of pairs available.

If γ or C depend on $\vec{h}$ only through its length $\|\vec{h}\|$, then Z is said to be *isotropic*, that is, $\gamma(\vec{h}) = \gamma(h)$ where $h = \|\vec{h}\|$. All pairs $(z(x_i), z(x_j))$ with $\|x_i - x_j\| = h$ can then be used to estimate $\gamma(h)$. In the isotropic case, the contour $\{\vec{h} : \gamma(\vec{h}) = k\}$ is a sphere. When this is not the case, Z is said to be *anisotropic*. Often anisotropy can be corrected by a transformation of coordinates. When this is the case, the random function Z is said to have *geometric anisotropy*. Correction of anisotropy by transformation of coordinates is possible when the contour $\{\vec{h} : \gamma(\vec{h}) = k\}$ can be approximated by an ellipse. In many applications $D \subset \mathbb{R}^3$ and in such cases, the contour $\{\vec{h} : \gamma(\vec{h}) = k\}$ is approximated by $\{\vec{h} : \frac{h_1^2}{a_1^2} + \frac{h_2^2}{a_2^2} + \frac{h_3^2}{a_3^2} = k\}$ where $\vec{h} = (h_1, h_2, h_3)^T$. By change of coordinates the vector $\vec{h} = (h_1, h_2, h_3)^T$ is transformed to $\vec{h}' = (h'_1, h'_2, h'_3)^T$ with $h'_1 = h_1, h'_2 = h_2 \cdot a_1/a_2, h'_3 = h_3 \cdot a_1/a_3$. A function $\tilde{\gamma}(\vec{h}') = \gamma(\vec{h}) \forall \vec{h}$ is defined such that the contour $\{\vec{h}' : \tilde{\gamma}(\vec{h}') = k'\}$ is given by $\{\vec{h}' : \frac{h'^2_1}{a_1^2} + \frac{h'^2_2}{a_1^2} + \frac{h'^2_3}{a_1^2} = k'\}$ that is, a sphere. To see this, consider the set $\{\vec{h}' : \tilde{\gamma}(\vec{h}') = k'\} = \{\vec{h}' : \gamma(\vec{h}) = k'\} = \{\vec{h}' : \frac{h'^2_1}{a_1^2} + \frac{h'^2_2}{a_2^2} + \frac{h'^2_3}{a_3^2} = c\}$ for an appropriate c because the contours of γ are ellipses. Multiplying by a_1^2 , one has $\{\vec{h}' : h'^2_1 + h'^2_2 a_1^2/a_2^2 + h'^2_3 a_1^2/a_3^2 = a_1^2 c\} = \{\vec{h}' : \frac{h'^2_1}{a_1^2} + \frac{h'^2_2}{a_1^2} + \frac{h'^2_3}{a_1^2} = c\}$ showing that the contours of $\tilde{\gamma}$ are spheres.

Another kind of anisotropy is called *zonal anisotropy* (Journel and Huijbregts 1978). Zonal anisotropy can occur when the random process Z is the sum of two or more independent random processes $Z_1, Z_2, \dots$, each with different geometric anisotropies. The semivariogram (or covariance) of Z is then the sum of the semivariograms (or covariances), respectively, of each of the independent random processes, that is, $\gamma(\vec{h}) = \gamma_1(\vec{h}) + \gamma_2(\vec{h}) + \dots$ where each $\gamma_i(\vec{h})$ may

have its own geometric anisotropy. In particular, one or more components of the random process Z may have highly extended ellipses of geometric anisotropy in one or more directions.

In data analysis, the experimental semivariograms $\hat{\gamma}(\vec{h})$ of Z are computed in several directions and the principal directions of variability are identified and can often be related to anisotropies in the underlying physical processes. When the random function Z is transitive, geometric anisotropy is indicated when the range of the variogram (or covariance) varies with direction. If geometric anisotropy is present, then the principal directions of variability are taken as the principal axes of the ellipse of geometric anisotropy. In the case of zonal anisotropy, the variogram of Z is modeled as the sum of more than one variograms, each with its own geometric anisotropy. *Semivariogram modeling* consists of fitting valid (conditional negative definite) functions to $\hat{\gamma}(\vec{h})$. Commonly parametric models such as the spherical, exponential, Gaussian, and nugget models are used for random functions that show transitive phenomena (Journel and Huijbregts 1978). Other valid models can also be used according to the nature of the random function Z . When the random function Z is second-order stationary, models of the covariance are immediately obtained from models of the semivariogram since $C(\vec{h}) = C(0) - \gamma(\vec{h})$.

When a random vector $\mathbf{Z}$ is studied, modeling of its semivariogram $\Gamma(\vec{h})$ and covariance $\Sigma(\vec{h})$ is done by obtaining the ij^{th} experimental cross-semivariograms and cross-covariances, $\hat{\gamma}_{ij}(\vec{h})$ and $\hat{C}_{ij}(\vec{h})$, respectively, where $\hat{\gamma}_{ij}(\vec{h}) = \frac{1}{2n} \sum_{\alpha=1}^n \left(z_i(x_\alpha) - z_i(x_\alpha + \vec{h}) \right) \left(z_j(x_\alpha) - z_j(x_\alpha + \vec{h}) \right)$ and $\hat{C}_{ij}(\vec{h}) = \frac{1}{n} \sum_{\alpha=1}^n z_i(x_\alpha) z_j(x_\alpha + \vec{h}) - m_i m_j$ with n being the number of available pairs, $m_i = \frac{1}{N} \sum_{\alpha=1}^N z_i(x_\alpha)$, and $m_j = \frac{1}{N} \sum_{\alpha=1}^N z_j(x_\alpha)$. The intrinsic model of coregionalization or the linear model of coregionalization may be used to guarantee consistency when such models are appropriate.

Kriging

One of the most important problems of geostatistics, in its simplest form, is the following: A stochastic process Z is observed at locations $x_\alpha, \alpha = 1, 2, \dots, N$, that is, realizations $z(x_1), z(x_2), \dots, z(x_N)$ of the random variables $Z(x_1), Z(x_2), \dots, Z(x_N)$ are available. The random variable $Z(x_0)$ corresponding to the location x_0 has not been observed and is to be predicted (or estimated) using the data at $x_1, x_2, \dots, x_N$.

Towards a solution, assume all random variables have finite variance and consider the class ζ of all random variables of the form $g(Z(x_1), Z(x_2), \dots, Z(x_N))$ with finite variance.

A reasonable predictor of $Z(x_0)$ is a member $Z^*(x_0)$ of the class ζ which minimizes $E[(Z(x_0) - Z^*(x_0))^2]$, the least squares estimator (Journal and Huijbregts 1978). The least squares estimator $Z^*(x_0)$ that is obtained turns out to be the conditional expectation $E[Z(x_0) | Z(x_1), Z(x_2), \dots, Z(x_N)]$. Evaluation of this conditional expectation, however, needs the $N + 1$ - variate joint distribution of $Z(x_0), Z(x_1), Z(x_2), \dots, Z(x_N)$. Unfortunately, most applications in geostatistics do not lend themselves to such modeling. This indicates that the class ζ is "too big." Choosing a smaller class leads to implementable solutions.

Linear Kriging

The simplest linear kriging solution considers the class ζ_0 of all functions of the type $\lambda_0 + \sum_{\alpha=1}^N \lambda_\alpha Z(x_\alpha)$ where, $\lambda_0, \lambda_1, \dots, \lambda_N$ are real numbers. The object is to choose the $\lambda_0, \lambda_1, \dots, \lambda_N$ so as to minimize the quantity $E[(Z(x_0) - Z^*(x_0))^2] =$

$E\left[Z(x_0) - \left(\lambda_0 + \sum_{\alpha=1}^N \lambda_\alpha Z(x_\alpha)\right)\right]^2$, termed the *estimation variance*. By differentiating the expression for variance of estimation with respect to λ_α , $\alpha = 1, 2, \dots, N$ and λ_0 the following equations are obtained for the optimal choice of λ_0 ,

$$\lambda_1, \dots, \lambda_N: E\left[\left(Z(x_0) - \left(\lambda_0 + \sum_{\beta=1}^N \lambda_\beta Z(x_\beta)\right)\right)Z(x_\alpha)\right] = 0, \\ \alpha = 1, 2, \dots, N, \text{ and } E\left[Z(x_0) - \left(\lambda_0 + \sum_{\alpha=1}^N \lambda_\alpha Z(x_\alpha)\right)\right] = 0.$$

These equations can be written as $\sum_{\beta=1}^N \lambda_\beta C(x_\beta, x_\alpha) = C(x_0, x_\alpha)$, $\alpha = 1, 2, \dots, N$ and $\lambda_0 = m(x_0) - \sum_{\alpha=1}^N \lambda_\alpha m(x_\alpha)$

where $C(x_\beta, x_\alpha) = \text{Cov}[Z(x_\beta), Z(x_\alpha)]$, $C(x_0, x_\alpha) = \text{Cov}[Z(x_0), Z(x_\alpha)]$, $m(x_\alpha) = E[Z(x_\alpha)]$ and $m(x_0) = E[Z(x_0)]$. Equivalently, using the relation $\gamma(\vec{h}) = C(0) - C(\vec{h})$, the preceding equations can be written in terms of the semi-

variogram as $\sum_{\beta=1}^N \lambda_\beta \gamma(x_\beta, x_\alpha) = \gamma(x_0, x_\alpha)$, $\alpha = 1, 2, \dots, N$ and $\lambda_0 = m(x_0) - \sum_{\alpha=1}^N \lambda_\alpha m(x_\alpha)$. The variance of estimation for the optimal solution, that is, $\text{Var}[Z(x_0) - Z^*(x_0)] = E[(Z(x_0) - Z^*(x_0))^2]$ is obtained as $C(0) - \sum_{\alpha=1}^N \lambda_\alpha C(x_0, x_\alpha)$ or as

$\sum_{\alpha=1}^N \lambda_\alpha \gamma(x_0, x_\alpha)$, (noting that $\gamma(0) = 0$). The variance of the optimal estimator, that is, $\text{Var}[Z^*(x_0)]$ is given by $\sum_{\alpha=1}^N \sum_{\beta=1}^N \lambda_\alpha \lambda_\beta C(x_\alpha, x_\beta) = \sum_{\alpha=1}^N \lambda_\alpha C(x_0, x_\alpha)$.

Geometrically, the optimal solution $Z^*(x_0)$ is the projection of $Z(x_0)$ on to ζ_0 and the preceding equations are precisely

the ones satisfied by the projection, that is, the vector $Z(x_0) - Z^*(x_0)$ is perpendicular to each member of ζ_0 . Geometrically, the variance of estimation is the norm of the vector $(Z(x_0) - Z^*(x_0))^2$, that is, $\|Z(x_0) - Z^*(x_0)\|^2$. The process of projecting $Z(x_0)$ onto ζ_0 is called *simple kriging* (Journal and Huijbregts 1978) and this optimal estimator is commonly denoted by $Z_{SK}^*(x_0)$. The variance of estimation is denoted by $\sigma_{SK}^2(x_0)$. A property of $Z_{SK}^*(x_0)$ is that it is unbiased, that is, $E[Z_{SK}^*(x_0) - Z(x_0)] = 0$ or, $E[Z_{SK}^*(x_0)] = E[Z(x_0)] = m(x_0)$. Unbiasedness is guaranteed because $E[Z_{SK}^*(x_0) - Z(x_0)] = 0$ gives $\lambda_0 = m(x_0) - \sum_{\alpha=1}^N m(x_\alpha)$, one of the equations of simple kriging.

If it is assumed that the stochastic process Z is second-order stationary, then $C(x_\alpha, x_\beta) = C(x_\alpha - x_\beta) \quad \forall \alpha, \beta$ and $\gamma(x_\alpha, x_\beta) = \gamma(x_\alpha - x_\beta) \quad \forall \alpha, \beta$ and the values of these quantities can be obtained from the covariance and semivariogram models of Z . Also, in this case, $m(x) = m \quad \forall x$ giving $\lambda_0 = \left(1 - \sum_{\alpha=1}^N \lambda_\alpha\right)m$.

When $m(x)$ is not constant, but is known everywhere, $\lambda_0 = m(x_0) - \sum_{\alpha=1}^N \lambda_\alpha m(x_\alpha)$ and it can be seen that the equations for obtaining the optimal estimator remain the same. This is expected since when $m(x)$ is known everywhere, by considering $Y(x) = Z(x) - m(x)$, the estimation procedure reduces to one where m is constant and known to be zero.

When m is unknown, but assumed to be constant, the subspace of $\zeta_1 \subset \zeta_0$ of all random variables of the type $\sum_{\alpha=1}^N \lambda_\alpha Z(x_\alpha)$, is considered, that is, λ_0 is taken to be zero.

This imposes the condition $\sum_{\alpha=1}^N \lambda_\alpha = 1$ and hence the projection of $Z(x_0)$ is done onto a linear manifold $\xi_1 \subset \zeta_1$. Since $\sum_{\alpha=1}^N \lambda_\alpha = 1$, $Z^*(x_0)$ is unbiased, that is, $E\left[\sum_{\alpha=1}^N \lambda_\alpha Z(x_\alpha) - Z(x_0)\right] =$

$\left(\sum_{\alpha=1}^N \lambda_\alpha - 1\right)m = 0$, irrespective of m . Thus, it is not required to estimate m .

The process of projecting $Z(x_0)$ onto ξ_1 is called *ordinary kriging* and the optimal estimator so obtained is called the ordinary kriging estimator, $Z_{OK}^*(x_0)$, with a corresponding variance of estimation $\|(Z(x_0) - Z^*(x_0))^2\| = \sigma_{OK}^2(x_0)$. Minimization of $E[(Z(x_0) - Z^*(x_0))^2]$ is done under the condition that $\sum_{\alpha=1}^N \lambda_\alpha = 1$. This is done using the method of Lagrange multipliers giving $\sum_{\beta=1}^N \lambda_\beta C(x_\beta, x_\alpha) - \mu = C(x_0, x_\alpha)$, $\alpha = 1, 2, \dots, N$ and $\sum_{\alpha=1}^N \lambda_\alpha = 1$, where μ is the Lagrange multiplier. The variance of ordinary kriging,

$\sigma_{OK}^2(x_0) = C(0) - \sum_{\alpha=1}^N \lambda_{\alpha} C(x_0, x_{\alpha}) + \mu$. Equivalently, in terms of the semivariogram the $N + 1$ equations of ordinary kriging are given by $\sum_{\beta=1}^N \lambda_{\beta} \gamma(x_{\beta}, x_{\alpha}) + \mu = \gamma(x_0, x_{\alpha})$, $\alpha = 1, 2, \dots, N$ and $\sum_{\alpha=1}^N \lambda_{\alpha} = 1$, with $\sigma_{OK}^2(x_0) = \sum_{\alpha=1}^N \lambda_{\alpha} \gamma(x_0, x_{\alpha}) + \mu$ (noting again that $\gamma(0) = 0$). When Z is intrinsic, the ordinary kriging equations in terms of the semivariogram must be used.

It can be shown that the ordinary kriging estimator is the simple kriging estimator with the unknown mean m replaced by m_{OK}^* , where $m_{OK}^* = \sum_{\alpha=1}^N \lambda_{\alpha}^m Z(x_{\alpha})$ is the ordinary kriging estimator of the mean $M = \frac{1}{N} \sum_{\alpha=1}^N Z(x_{\alpha})$. In other words, $Z_{OK}^*(x_0) = m_{OK}^* + \sum_{\alpha=1}^N \lambda_{\alpha} (Z(x_{\alpha}) - m_{OK}^*)$ where λ_{α} , $\alpha = 1, 2, \dots, N$ are solutions to the simple kriging system with $\lambda_0 = \left(1 - \sum_{\alpha=1}^N \lambda_{\alpha}\right) m_{OK}^*$.

In many situations, $m(x)$ varies with x and is unknown. If it is assumed that $m(x) = \sum_{l=0}^L a^l f^l(x)$, for some basis functions $f^0, f^1, \dots, f^L$, where the a^l 's are unknown, then it is possible to obtain an unbiased optimal predictor of $Z(x_0)$ without estimating the a^l 's. One choice for the basis functions $f^0, f^1, \dots, f^L$ is a set of monomials in x with $f^0(x) = 1$. The required estimator of the type $Z^*(x_0) = \sum_{\alpha=1}^N w_{\alpha} Z(x_{\alpha})$ is one where the w_{α} 's satisfy the unbiasedness of the estimator $Z^*(x_0)$. Since $E[Z^*(x_0) - Z(x_0)] = \sum_{\alpha=1}^N w_{\alpha} \sum_{l=0}^L f^l(x_{\alpha}) - \sum_{l=0}^L f^l(x_0) = 0$ this gives the required unbiasedness conditions $\sum_{l=0}^L w_{\alpha} f^l(x_{\alpha}) = f^l(x_0)$, $l = 0, 1, \dots, L$. Geometrically, since $m(x)$ is unknown, and $L + 1$ unbiasedness conditions are introduced, a subspace $\xi_L \subset C_1$ with L linear constraints is considered to project $Z(x_0)$. This projection is called *universal kriging*. The optimal estimator $Z^*(x_0)$, termed the universal kriging estimator is a member of ξ_L and is given by $\sum_{\beta=1}^N \lambda_{\beta} C(x_{\beta}, x_{\alpha}) - \sum_{l=0}^L \mu_l f^l(x_{\alpha})$, $\alpha = 1, 2, \dots, N$, and $\sum_{\alpha=1}^N \lambda_{\alpha} f^l(x_{\alpha}) = f^l(x_0)$, $l = 0, 1, \dots, L$ with variance of estimation given by $\sigma_{UK}^2 = C(0) - \sum_{\alpha=1}^N \lambda_{\alpha} C(x_0, x_{\alpha}) + \sum_{l=0}^L \mu_l f^l(x_0)$. The μ_l 's in the universal kriging equations are Lagrange multipliers. The equations of universal kriging can similarly also be obtained in terms of the semivariogram as in previous cases. As discussed earlier, $C(x_{\alpha}, x_{\beta})$ and $\gamma(x_{\alpha}, x_{\beta})$ cannot be estimated directly from data since $m(x)$ is unknown. Universal kriging is

possible only when approximate models of the covariance or semivariogram of the random function can be constructed.

Another approach is to model Z as an intrinsic random function of order k ($IRF - k$) with $m(x) = \sum_{l=0}^L a^l f^l(x)$ and use authorized models which give a second-order stationary random function $Z_W(s) = \sum_{\alpha=0}^L w_{\alpha} Z(x_{\alpha} + s) \quad \forall s$ with w_{α} , $\alpha = 1, 2, \dots, n$ satisfying $\sum_{\alpha=1}^n w_{\alpha} f^l(x_{\alpha} + s) = f^l(x_0 + s) \quad \forall s$, $l = 0, 1, \dots, L$. The random function Z has generalized covariance $K(\vec{h})$. The set of optimal equations obtained is identical to that of universal kriging except that the generalized covariance $K(x_{\alpha}, x_{\beta}) = K(x_{\alpha} - x_{\beta})$ is used instead of $C(x_{\alpha}, x_{\beta})$. The μ_l 's in the $IRF - k$ kriging equations are Lagrange multipliers that ensure that the λ 's lead to an authorized linear combination. As mentioned earlier, in the case of $IRF - 0$, $K(\vec{h}) = -\gamma(\vec{h})$. Geometrically, the $IRF - k$ estimator $Z_{IRF-k}^*(x_0)$ is the projection of $Z(x_0)$ onto ξ_L .

Cokriging

Let the random process $\mathbf{Z} = \{\mathbf{Z}(x), x \in D\}$ be observed at x_{α} , $\alpha = 1, 2, \dots, N$ and let $\mathbf{Z}(x_{\alpha}) = (Z_1(x_{\alpha}), Z_2(x_{\alpha}), \dots, Z_p(x_{\alpha}))^T$ be the p -dimensional vector observed at x_{α} . The random vector $\mathbf{Z}(x_0) = (Z_1(x_0), Z_2(x_0), \dots, Z_p(x_0))^T$ is unobserved. For brevity of notation, denote by Z_j^z the j^{th} component of $\mathbf{Z}(x_{\alpha})$, $\alpha = 0, 1, 2, \dots, N$ and let $Z_i^{0*} = \lambda_0^i + \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i Z_j^z$ be the estimator of Z_i^0 where $\lambda_{j\alpha}^i$ are coefficients of Z_j^z , $j = 1, 2, \dots, p$, and $\alpha = 1, 2, \dots, N$ in the estimation of Z_i^0 , and λ_0^i is a constant. Since the unbiasedness condition for the estimator of Z_i^0 is given by $E[Z_i^0 - Z_i^{0*}] = E\left[Z_i^0 - \lambda_0^i - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i Z_j^z\right] = 0$, $\lambda_0^i = m_i^0 - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i m_j^z$ where $m_i^0 = E[Z_i^0]$ and $m_j^z = E[Z_j^z]$, $j = 1, 2, \dots, p$; $\alpha = 1, 2, \dots, N$. The optimal values of the $\lambda_{j\alpha}^i$ that minimize $E[Z_i^0 - Z_i^{0*}]^2 = E\left[Z_i^0 - \lambda_0^i - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i Z_j^z\right]^2$ are then given by $\sum_{\beta=1}^N \sum_{k=1}^p \lambda_{k\beta}^i \text{Cov}(Z_k^z, Z_j^z) = \text{Cov}(Z_i^0, Z_j^z)$, $j = 1, 2, \dots, p$; $\alpha = 1, 2, \dots, N$. The optimal estimator Z_i^{0*} so obtained is called the *simple cokriging* estimator. The variance of estimation of this estimator is given by $\sigma_{COK,i}^2 = E[Z_i^0 - Z_i^{0*}]^2 = C_i(0) - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i \text{Cov}(Z_i^0, Z_j^z)$. If $\mathbf{Z}$ is a second-order stationary random process, $m_j = E[Z_j^z]$, $j = 1, 2, \dots, p$; $\alpha = 0, 1, \dots, N$, $\text{Cov}(Z_k^z, Z_j^z) = C_{kj}(x_{\beta} - x_{\alpha})$ and $\text{Cov}(Z_i^0, Z_j^z) = C_{ij}(x_0 - x_{\alpha})$.

When $m_j = E[Z_j^z]$, $j = 1, \dots, p$; $\alpha = 0, 1, \dots, N$ are unknown, but constant for each component of $\mathbf{Z}$, as in the ordinary kriging case, the unbiasedness condition for the estimator Z_i^{0*} of Z_i^0 is obtained as $E[Z_i^0 - Z_i^{0*}] = E[Z_i^0 - \lambda_0^i - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i Z_j^z] = \left(m_i - \lambda_0^i - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i m_j \right) = \left(m_i - \lambda_0^i - \sum_{\alpha=1}^N \lambda_{i\alpha}^i m_i - \sum_{j \neq i} \sum_{\alpha=1}^N \lambda_{j\alpha}^i m_j \right) = 0$. The preceding

equation is satisfied for any choice of m_i, m_j only when $\lambda_0^i = 0$, with $\sum_{\alpha=1}^N \lambda_{i\alpha}^i = 1$ and $\sum_{\alpha=1}^N \lambda_{j\alpha}^i = 0, \forall j \neq i$. The optimal equations for minimization of $E[Z_i^0 - Z_i^{0*}]^2$ subject to the preceding constraints are obtained as

$$\left\{ \begin{array}{l} \sum_{\beta=1}^N \sum_{k=1}^p \lambda_{k\beta}^i \text{Cov}(Z_k^\beta, Z_j^z) - \mu_k = \text{Cov}(Z_i^0, Z_j^z), \quad j = 1, 2, \dots, p; \quad \alpha = 1, 2, \dots, N \\ \sum_{\alpha=1}^N \lambda_{k\alpha}^i = 0, \quad k \neq i \\ \sum_{\alpha=1}^N \lambda_{i\alpha}^i = 1 \end{array} \right.$$

where $\mu_k, k = 1, 2, \dots, p$ are Lagrange multipliers.

The estimator Z_i^{0*} obtained using the optimal weights obtained from the preceding equations is called the *ordinary cokriging estimator*.

If all variables are not available at every location, one may have $n_j \leq N$ observations on the variable j . Let $\alpha_j = 1, 2, \dots, n_j$ denote the locations where the process Z_j has been observed. The above ordinary cokriging equations are then given by

$$\left\{ \begin{array}{l} \sum_{k=1}^p \sum_{\beta_k=1}^{n_k} \lambda_{k\beta_k}^i \text{Cov}(Z_k^{\beta_k}, Z_j^{\alpha_j}) - \mu_k = \text{Cov}(Z_i^0, Z_j^{\alpha_j}), \quad j = 1, 2, \dots, p; \quad \alpha_j = 1, 2, \dots, n_j \\ \sum_{\alpha_k=1}^{n_k} \lambda_{k\alpha_k}^i = 0, \quad k \neq i \\ \sum_{\alpha_i=1}^{n_i} \lambda_{i\alpha_i}^i = 1 \end{array} \right.$$

These equations also result if in the previous set of equations $\lambda_{j\alpha}^i$ is taken to be zero if Z_j is not observed at location x_α .

When the random process $\mathbf{Z}$ is second-order stationary, the cokriging equations can be written as

$$\text{Cov}(Z_k^\beta, Z_j^\alpha) = C_{kj}(x_\alpha - x_\beta), \quad \forall k, j = 0, 1, \dots, p; \quad \alpha, \beta = 0, 1, \dots, N \text{ with} \\ \text{Var}(Z_j^z) = C_j(0), \quad j = 1, 2, \dots, p; \quad \alpha = 0, 1, \dots, N$$

The variance of the ordinary cokriging estimator is given by $\sigma_{\text{COK},i}^2 = E[Z_i^0 - Z_i^{0*}]^2 = C_i(0) - \sum_{\alpha=1}^N \sum_{j=1}^p \lambda_{j\alpha}^i C_{ij}(x_0 - x_\alpha) + \mu_i$, or $\sigma_{\text{COK},i}^2 = E[Z_i^0 - Z_i^{0*}]^2 = C_i(0) - \sum_{j=1}^p \sum_{\alpha_k=1}^{n_j} \lambda_{j\alpha_k}^i C_{ij}(x_0 - x_{\alpha_k}) + \mu_i$, depending on whether the data is isotopic or heterotopic.

In matrix form, considering simple cokriging in the second-order stationary isotopic case where all p variables are observed at all data locations, let $\mathbf{\Lambda}$ be a $(Np \times p)$ dimensional matrix of $N \times p$ weights for the simple cokriging of the vector $(Z_1^0, Z_2^0, \dots, Z_p^0)^T$. Let $\mathbf{Z}_D$ be the $(Np \times 1)$ vector of observations ordered by locations with p random variables at each of the N locations (i.e., the first p elements of $\mathbf{Z}_D$ are the p random variables observed at location x_1 , the next set being the p random variables observed at location x_2 , and so on). The $(Np \times Np)$ covariance matrix of $\mathbf{Z}_D$ is given by $\mathbf{\Sigma}_D$, say, where $\mathbf{\Sigma}_D = [C_{jk}(\alpha, \beta)]$, with $C_{jk}(\alpha, \beta) = \text{Cov}(Z_j^\alpha, Z_k^\beta), j, k = 1, 2, \dots, p; \quad \alpha, \beta = 1, 2, \dots, N$. If $\mathbf{Z}^0$ denotes the $(p \times 1)$ vector at location x_0 that is to be predicted, the simple cokriging vector $\mathbf{Z}^{0*}$ is given by $\mathbf{Z}^{0*} = \mathbf{\Lambda}^T \mathbf{Z}_D$, where $\mathbf{\Lambda} = \mathbf{\Sigma}_D^{-1} \mathbf{C}_0$ with $\mathbf{C}_0$ being the $(Np \times 1)$ vector whose elements

are given by $C_{ij}(0, \alpha) = \text{Cov}(Z_i^0, Z_j^\alpha)$, $\alpha = 1, 2, \dots, N$; $j = 1, 2, \dots, p$. When data locations and locations where predictions are to be made are grouped suitably into "blocks," block-matrix operations can be used effectively to obtain cokriged estimated at unobserved data locations.

An alternate way of ordering, the $(Np \times p)$ vector $\mathbf{Z}_D$ of observations is to do it random variable-wise with the first N elements of $\mathbf{Z}_D$ being $(Z_1^1, Z_1^2, Z_1^3, \dots, Z_1^N)^T$ followed by $(Z_2^1, Z_2^2, Z_2^3, \dots, Z_2^N)^T$ and so on. The $(Np \times Np)$ covariance matrix of $\mathbf{Z}_D$ is given by Σ_{D^*} , say, where $\Sigma_{D^*} =$

$$[C_{jk}(\alpha, \beta)] = \begin{bmatrix} C_{11}(\alpha, \beta) & C_{12}(\alpha, \beta) & \dots & C_{1p}(\alpha, \beta) \\ C_{21}(\alpha, \beta) & C_{22}(\alpha, \beta) & \dots & C_{2p}(\alpha, \beta) \\ \vdots & \vdots & \ddots & \vdots \\ C_{p1}(\alpha, \beta) & C_{p2}(\alpha, \beta) & \dots & C_{pp}(\alpha, \beta) \end{bmatrix}.$$

The matrices $C_{jk}(\alpha, \beta)$ give the covariance between vectors $(Z_j^1, Z_j^2, Z_j^3, \dots, Z_j^N)^T$ and $(Z_k^1, Z_k^2, Z_k^3, \dots, Z_k^N)^T$. The simple cokriging equations remain the same and the estimator is given by $\mathbf{Z}^{0*} = \Lambda^T \mathbf{Z}_D$ where $\Lambda = \Sigma_{D^*}^{-1} \mathbf{C}_0$ with $\mathbf{C}_0$ being the $(Np \times 1)$ vector whose elements are given by $C_{ij}(0, \alpha) = \text{Cov}(Z_i^0, Z_j^\alpha)$, $j = 1, 2, \dots, p$; $\alpha = 1, 2, \dots, N$. The p -dimensional vector of simple cokriging variances is given by $\sigma_{\text{COK}}^2 = \mathbf{C}(0) - \text{diag}[\Lambda^T \mathbf{C}_0]$ where $\mathbf{C}(0)$ is a p -dimensional vector of variances of Z_i^0 , $i = 1, 2, \dots, p$.

Kriging of $Z_V(x_0)$ and Functions of $Z(x_0)$

If it is required to predict the random function W at x_0 (i.e., $W(x_0)$ denoted by W^0) using observations on the random function Z at x_α , $\alpha = 1, 2, \dots, N$, denoted here as Z^α , $\alpha = 1, 2, \dots, N$, it is clear from the simple and ordinary kriging equations that minimization of $E[W^0 - W^{0*}]^2$ where $W^{0*} = \lambda_0 + \sum_{\alpha=1}^N \lambda_\alpha Z^\alpha$ can only be done when $\text{Cov}(W^0, Z^\alpha)$, $\alpha = 1, 2, \dots, N$ is known. As an example, let $W^0 = Z_V^0$ with $Z_V^0 \equiv Z_V(x_0) = \frac{1}{|V|} \int_V Z(s) ds$ where V is a volume centered at x_0 . Here, $\text{Cov}(Z_V^0, Z^\alpha) = \frac{1}{|V|} \int_V \text{Cov}(x_s, x_\alpha) ds$ (or if $Z_V^0 = \frac{1}{N} \sum_{i=1}^N Z^{s_i}$, $\text{Cov}(Z_V^0, Z^\alpha) = \frac{1}{N} \sum_{i=1}^N \text{Cov}(x_{s_i}, x_\alpha)$) where x_{s_i} are chosen points located in the volume V centered at x_0 . When Z is a second-order stationary random function, and $C(\vec{h})$ or $\gamma(\vec{h})$ have been modeled, $\text{Cov}(Z_V^0, Z^\alpha) = \frac{1}{|V|} \int_V C(x_s - x_\alpha) ds$, (or $\text{Cov}(Z_V^0, Z^\alpha) = \frac{1}{N} \sum_{i=1}^N C(x_{s_i} - x_\alpha)$). The solution to the simple or ordinary kriging system is obtained as before. The variance of estimation by simple and ordinary kriging are given by $\sigma_{\text{SK}}^2 = \bar{C}(V, V) - \sum_{\alpha=1}^N \lambda_\alpha \bar{C}(V, \alpha)$, or $\sigma_{\text{OK}}^2 = \bar{C}(V, V) - \sum_{\alpha=1}^N \lambda_\alpha \bar{C}(V, \alpha) + \mu$, respectively, where $\bar{C}(V, V) = \text{Var}(Z_V(x_0))$

$$= \frac{1}{|V|^2} \int_V \int_V \text{Cov}(x_s, x_{s'}) ds ds' \quad (\text{or when } Z_V^0 = \frac{1}{N} \sum_{i=1}^N Z^{s_i}, \bar{C}(V, V) = \text{Var}(Z_V(x_0)) = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \text{Cov}(x_{s_i}, x_{s_j})).$$

When Z is a second-order stationary random function, these can be written as $\bar{C}(V, V) = \frac{1}{|V|^2} \int_V \int_V C(x_s - x_{s'}) ds ds'$ or $\bar{C}(V, V) = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N C(x_{s_i} - x_{s_j})$.

If a function $W(x_0) = g(Z(x_0))$ is of interest, the estimation of $W(x_0)$ by $W^{0*} = \lambda_0 + \sum_{\alpha=1}^N \lambda_\alpha W^\alpha$, where $W^\alpha = g(Z(x_\alpha))$, is considered and the optimal solution is obtained by minimizing $E[W^0 - W^{0*}]^2$. The required covariances, $\text{Cov}(W(x_\alpha), W(x_\beta))$, $\alpha = 0, 1, \dots, N$; $\beta = 0, 1, \dots, N$, are obtained by modeling the random function $W = g(Z)$. If second-order stationarity of W is assumed, the covariance of W can be modeled and the kriging of $W(x_0) = g(Z(x_0))$ reduces to the simple and ordinary kriging cases discussed earlier.

A function g that is often used in geostatistics is the indicator function $I_{Z(x) \leq z}(x) = \begin{cases} 1 & \text{if } Z(x) \leq z \\ 0 & \text{otherwise} \end{cases}$. To estimate $W = \{W(x) \equiv I_{Z(x) \leq z}(x), x \in D\}$ at unobserved locations, its covariance or semivariogram (i.e., the indicator-covariance or indicator-semivariogram) are required. Depending on the stationarity assumptions made on the random function W , simple or ordinary kriging is used to obtain the estimator and the corresponding procedures are called *simple kriging of indicators* or *ordinary kriging of indicator* respectively.

If the p -dimensional indicator random process $\mathbf{W} = \{\mathbf{W}(x) \equiv (I_{Z(x) \leq z_i}(x), i = 1, 2, \dots, p)^T, x \in D\}$ is considered, one option to estimate the random vector $\mathbf{W}(x_0) = (I_{Z(x_0) \leq z_i}(x_0), i = 1, 2, \dots, p)^T$ at location x_0 using sets of indicator random variables $\mathbf{W}(x_\alpha) = (I_{Z(x_\alpha) \leq z_i}(x_\alpha), i = 1, 2, \dots, p)^T$; $\alpha = 1, 2, \dots, N$ at locations x_α where Z has been observed, is to use simple or ordinary cokriging depending on stationarity assumptions on $\mathbf{W}$. To obtain the optimal estimator $\mathbf{W}^*(x_0) = (I_{Z(x_0) \leq z_i}^*(x_0), i = 1, 2, \dots, p)^T$ simple or ordinary cokriging are used. The terms *simple cokriging of indicators* and *ordinary cokriging of indicators*, respectively, are used for these procedures. To perform the cokriging, auto- and cross-indicator-covariances or indicator-semivariograms need to be modeled.

It is relevant to note here that $E[I_{Z(x) \leq z}(x)] = F_{Z(x)}(z)$ where $F_{Z(x)}(z)$ is the frequency distribution function of $Z(x)$ evaluated at z and that $E[I_{Z(x) \leq z}(x) I_{Z(x+\vec{h}) \leq z'}(x+\vec{h})] =$

$F^{\vec{h}}(z, z')$, say is the joint distribution of the random variables $(Z(x), Z(x + \vec{h}))$ evaluated at z and z' . The cokriging of indicators gives an estimate $F_{Z(x)}^*(z) | N$ for $E[I_{Z(x) \leq z}(x) | Z(x_\alpha) = z_\alpha, \alpha = 1, 2, \dots, N] = F_{Z(x)}(z) | N$, say, for a discrete set of values of z , where $F_{Z(x)}(z) | N$ is the conditional distribution of $Z(x) | Z(x_\alpha) = z_\alpha, \alpha = 1, 2, \dots, N$. For details, one may see Journel (1983, 1984).

Non-Parametric Estimation: Multiple Indicator Kriging

Let $z(x_\alpha), \alpha = 1, 2, \dots, N$ be observations on Z at $x_1, x_2, \dots, x_N$.

Consider the function $I_{Z(x) \leq z}(x) = \begin{cases} 1 & \text{if } Z(x) \leq z \\ 0 & \text{otherwise} \end{cases} = I(x; z)$,

say, and let $I^*(x; z | N)$ be the (ordinary indicator kriging) estimate of $I(x; z)$ at locations x where Z has not been observed.

Define a partition of the range of Z with appropriately chosen nodes $z_1 < z_2 < \dots < z_K$ and define $F^*(x; z | N) =$

$$\begin{cases} 0, & z < z_1 \\ I^*(x; z_i | N), & z_i \leq z < z_{i+1}, i < K \\ 1, & z \geq z_K \end{cases}$$

is an estimate of the conditional distribution function at x given the N data. An estimate $\phi^*(Z(x))$ of $\phi(Z(x))$, a function of $Z(x)$, is obtained as $E^*[\phi(Z(x))]$ where E^* denotes expectation computed under $F^*(x; z | N)$, that is,

$$E^*[\phi(Z(x))] = \sum_{i=1}^K \phi(z'_i) (F^*(x, z_{i+1} | N) - F^*(x, z_i | N)), \text{ where,}$$

z'_i is a chosen value in the interval $[z_i, z_{i+1}]$. This estimation procedure is called *multiple indicator kriging (MIK)*.

The MIK procedure is widely practiced because of ease of use and its ability to handle outliers. Modifications of the procedure have been used to incorporate information from “soft” categorical data. In MIK, estimates $I^*(x; z | N)$ are obtained by ordinary kriging (and not by cokriging) thereby losing some information contained in the cross-indicator covariances. Post-kriging correction of $I^*(-x; z | N)$ may be required to ensure monotonicity of $F^*(-x; z | N)$. This may occur at locations where the indicator variograms or covariances may not accurately capture local spatial structure of the regionalization. One other problem encountered in MIK is the problem of de-structuring of the variograms at high cut-offs due to sparse data of high values (Matheron 1982). A practical solution to this problem is to use the structure of the indicator-variogram at the median (median-indicator) for all indicators. For details of various techniques used in the indicator-based estimation procedures, one may see and Goovaerts (1997). Another way of addressing the loss of information in indicator kriging is the technique of probability kriging where the cross-covariances between the indicators and Z are modeled and utilized for cokriging the indicator functions.

Projection onto Larger Spaces

Consider the space ζ of all random variables of the form $g(Z(x_1), Z(x_2), \dots, Z(x_N))$ with finite variances. Since random variables can be added and multiplied by real numbers a vector-space structure may be imposed on ζ in a natural way. Since random variables can be multiplied, an inner product may be defined as follows: For X, Y in ζ , $\langle X, Y \rangle = E[XY]$, the uncentered covariance between X and Y . If $Z(x_0) \equiv Z^0$, say lies outside ζ , and Z_ζ^{0*} is its projection on ζ , Z_ζ^{0*} is characterized by the residual $Z^0 - Z_\zeta^{0*}$ being orthogonal to every member of ζ , that is, $\langle Z^0 - Z_\zeta^{0*}, X \rangle = 0$ for all $X \in \zeta$. Similarly, if ζ_D is a subspace of ζ and Z is to be projected into ζ_D , the projection is $Z_{\zeta_D}^{0*} \in \zeta_D$ and satisfies $\langle Z^0 - Z_{\zeta_D}^{0*}, H \rangle = 0, \forall H \in \zeta_D$. The variance of estimation with respect to an estimator Z^{0*} is given by $\|(Z^0 - Z^{0*})^2\|$.

A property of the projection is that $\|(Z^0 - Z_\zeta^{0*})^2\| \leq$

$$\|(Z^0 - Z_\xi^{0*})^2\| \text{ for } \xi \subset \zeta \text{ where } Z_\xi^{0*} \text{ is the projection of } Z^0$$

onto ξ . Linear kriging estimators discussed previously are projections onto the space ζ_0 for linear functions of $Z(x_1), Z(x_2), \dots, Z(x_N)$ or subsets of ζ_0 , where $\zeta_0 \subset \zeta_D \subset \zeta$. For the purpose of reducing variance of estimation, it is desirable to project onto the largest space possible. Projection of Z^0 onto ζ requires knowledge of the $N + 1$ -variate joint distribution of $Z(x_0), Z(x_1), Z(x_2), \dots, Z(x_N)$ which is generally unavailable. However, if the random process Z is modeled as a Gaussian process, this joint distribution becomes available as part of the assumption and therefore projection onto ζ is possible.

As mentioned earlier, if Z is a Gaussian process, then all the necessary joint distributions are available and Z^0 may be predicted by the conditional expectation $E[Z^0 | z^1, z^2, \dots, z^N]$ given by $\int_{-\infty}^{\infty} z g(z | z^1, z^2, \dots, z^N) dz$ where $g(z | z^1, z^2, \dots, z^N)$

is the Gaussian density function of the random variable $Z^0 | z^1, z^2, \dots, z^N$ with mean given by z_{SK}^* , the simple kriging of Z^0 using $z^1, z^2, \dots, z^N$ and variance given by σ_{SK}^2 , the variance of estimation of simple kriging. The conditional expectation $E[Z^0 | Z^1, Z^2, \dots, Z^N] = Z_{SK}^*$ and the conditional variance is σ_{SK}^2 are optimal in the bigger class ζ .

If the random process Z cannot be modeled as a Gaussian process, there may exist a function ϕ such that $Y = \phi(Z)$ is a Gaussian process. This is examined in section “Disjunctive Kriging in the Bivariate Gaussian Model” and “Disjunctive Kriging” deals with the projection of Z^0 onto a space ζ_D that is larger than ζ_0 .

Disjunctive Kriging

In disjunctive kriging, the subspace ζ_D , the set of all random variables of the form $\sum_{\alpha=1}^N h_\alpha(Z^\alpha)$ is considered, where $h_1, h_2, \dots, h_N$ are functions of one variable and $Z^\alpha \equiv Z(x_\alpha), \alpha = 0, 1, \dots, N$.

To project $g(Z^0)$ onto ζ_D the projection $g(Z^0)^* = \sum_{\alpha=1}^N \Lambda_\alpha(Z^\alpha)$ satisfies

$\left\langle \sum_{\alpha=1}^N \Lambda_\alpha(Z^\alpha) - g(Z^0), H \right\rangle = 0$ for all $H \in \zeta_D$. Equivalently, $\left\langle \sum_{\alpha=1}^N \Lambda_\alpha(Z^\alpha), H \right\rangle = \langle g(Z^0), H \rangle$ for all $H \in \zeta_D$.

This holds for all $H \in \zeta_D$, $\left\langle \sum_{\alpha=1}^N \Lambda_\alpha(Z^\alpha), h_\beta(Z^\beta) \right\rangle = \langle g(Z^0), h_\beta(Z^\beta) \rangle$, $\beta = 1, 2, \dots, N$ and for all functions h_β of Z^β . The projection of $g(Z^0)^* = \sum_{\alpha=1}^N \Lambda_\alpha(Z^\alpha)$ onto ζ_β and the projection of $g(Z^0)$ onto ζ_β , where ζ_β is the vector space of all random variables $h_\beta(Z^\beta)$ of Z^β coincide for each $\beta = 1, 2, \dots, N$. In other words, $E[g(Z^0)^* | Z^\beta] = E[g(Z^0) | Z^\beta]$, $\beta = 1, 2, \dots, N$. This set of equations are the equations for disjunctive kriging and are called the *DK-equations* (Matheron 1976a).

The DK-equations involve bivariate distributions of pairs of random variables (Z^0, Z^β) and (Z^α, Z^β) , $\alpha, \beta = 1, 2, \dots, N$ and hence these sets of bivariate distributions need to be modeled appropriately.

Bivariate Distributions and Isofactorial Models

To facilitate evaluation of conditional expectation of bivariate distributions, it is necessary to model the bivariate distributions of each pair of random variables involved in the estimation procedure. Some properties of bivariate distributions are useful for this purpose and are considered in the sequel.

Let X and Y be random variables with joint probability function given by $f(x, y)$. Let $f_1(x)$ and $f_2(y)$ denote the marginals of the random variables. Let $L_2(X)$ and $L_2(Y)$ be the vector-spaces of all functions of X and Y , respectively, that are square-integrable, that is, with finite variance. Let $\{\chi_i^{(1)}, i = 0, 1, 2, \dots\}$ and $\{\chi_j^{(2)}, j = 0, 1, 2, \dots\}$ be orthogonal functions such that any member $g(X)$ and $h(Y)$ of $L_2(X)$ and $L_2(Y)$, respectively, can be written as $\sum_{n=0}^{\infty} a_n \chi_n^{(1)}(X)$ and $\sum_{n=0}^{\infty} b_n \chi_n^{(2)}(Y)$, where $a_n = E[g(X) \chi_n^{(1)}(X)]$, and $b_n = E[h(Y) \chi_n^{(2)}(Y)]$. If X and Y are absolutely continuous random variables: $a_n = \int_{-\infty}^{\infty} g(x) \chi_n^{(1)}(x) f_1(x) dx$ and $b_n = \int_{-\infty}^{\infty} h(y) \chi_n^{(2)}(y) f_2(y) dy$. The functions $\{\chi_i^{(1)}, i = 0, 1, 2, \dots\}$ and $\{\chi_j^{(2)}, j = 0, 1, 2, \dots\}$ form an orthonormal basis of $L_2(X)$ and $L_2(Y)$, respectively. Taking $\chi_0^{(1)} = \chi_0^{(2)} = 1$, the orthonormality of these basis-functions implies the following: (i) $E[\chi_n^{(1)}(X)] = E[\chi_n^{(2)}(Y)] = 0$, $n = 1, 2, \dots$, (ii) $E[\chi_n^{(1)}(X)]^2 = E[\chi_n^{(2)}(Y)]^2 = 1$, $n = 1, 2, \dots$, (iii) $E[\chi_n^{(1)}(X) \chi_m^{(1)}(X)] = E[\chi_n^{(2)}(Y) \chi_m^{(2)}(Y)] = 0$ $n \neq m$.

If $w(x, y) = \frac{f(x, y)}{f_1(x)f_2(y)}$ is such that $\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} w(x, y)^2 f_1(x) f_2(y) dx dy = E[w(x, y)] < \infty$, then the joint probability function

can be written as $f(x, y) = f_1(x) f_2(y) \left[1 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} T_{ij}^{XY} \chi_i^{(1)}(x) \chi_j^{(2)}(y) \right]$ where, $T_{ij}^{XY} = E[\chi_i^{(1)}(X) \chi_j^{(2)}(Y)]$. The bivariate distribution is said to be *isofactorial* if $E[\chi_i^{(1)}(X) \chi_j^{(2)}(Y)] = 0$ $i \neq j$, in which case $f(x, y) = f_1(x) f_2(y) \left[1 + \sum_{i=1}^{\infty} T_{ii}^{XY} \chi_i^{(1)}(x) \chi_i^{(2)}(y) \right]$.

Consider the second-order stationary random function Z with marginal $f_1 = f_2 = f$. The bivariate distribution $f^{\alpha\beta}(x, y)$ of $Z(x_\alpha)$ and $Z(x_\beta)$ is given by $f^{\alpha\beta}(x, y) = f(x) f(y) \left[1 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} T_{ij}^{\alpha\beta} \chi_i(x) \chi_j(y) \right]$ and the conditional distribution of $Z(x_\alpha) | Z(x_\beta) = y$ by $f^{\alpha|\beta}(x|y) = f(x) \times \left[1 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} T_{ij}^{\alpha\beta} \chi_i(x) \chi_j(y) \right]$.

The DK Equations

Let x_0 be a location where the second-order random process Z is to be predicted. Let $g(Z(x_0)) \equiv g(Z^0)$, say, a function with finite variance, be a function to be estimated. Clearly, $g(Z^0) \in L_2(Z^0)$ and hence this function can be written as $\sum_{n=0}^{\infty} a_n \chi_n(Z^0)$, where $a_n = E[g(Z^0) \chi_n(Z^0)]$. The projection of a linear combination of functions onto a vector-space is the linear combination of the projection of each function onto that vector-space. Therefore, to project $g(Z^0) = \sum_{n=0}^{\infty} a_n \chi_n(Z^0)$ onto the space ζ_D generated by functions of the type $\sum_{\alpha=1}^N h_\alpha \left(Z(x_\alpha) \equiv \sum_{\alpha=1}^N h_\alpha(Z^\alpha) \right)$, say, it is enough to project each $\chi_n(Z^0)$, $n = 1, 2, \dots$ onto ζ_D . If $\chi_n^*(Z^0)$, $n = 1, 2, \dots$, is the projection of $\chi_n(Z^0)$ onto ζ_D , then the projection $g(Z^0)^*$ of $g(Z^0)$ onto ζ_D is given by $g(Z^0)^* = \sum_{n=0}^{\infty} a_n \chi_n^*(Z^0)$. In practice $g(Z^0)$ is approximated by $g(Z^0) = \sum_{n=0}^M a_n \chi_n(Z^0)$ and its estimator by $g(Z^0)^* = \sum_{n=0}^M a_n \chi_n^*(Z^0)$ where M is chosen so that $Var[g(Z^0)] = \sum_{n=1}^{\infty} a_n^2$ can be approximated to the desired level by $\sum_{n=1}^M a_n^2$.

The projection $\chi_n^*(Z^0) \in \zeta_D$ and hence $\chi_n^*(Z^0) = \sum_{\alpha=1}^N \Lambda_\alpha^{(n)}(Z^\alpha)$, where $\Lambda_\alpha^{(n)}(Z^\alpha) = \sum_{j=0}^{\infty} \lambda_{j\alpha}^{(n)} \chi_j(Z^\alpha)$. This gives $\chi_n^*(Z^0) = \sum_{\alpha=1}^N \sum_{j=0}^{\infty} \lambda_{j\alpha}^{(n)} \chi_j(Z^\alpha)$. The projection $\chi_n^*(Z^0)$ is characterized by $E[\chi_n^*(Z^0) | Z^\beta] = E[\chi_n(Z^0) | Z^\beta]$, $\beta = 1, 2, \dots, N$. Since $E[\chi_n^*(Z^0) | Z^\beta]$ and $E[\chi_n(Z^0) | Z^\beta] \in \zeta_{Z^\beta}$, (where ζ_{Z^β} is the space of all single-variable functions of Z^β (i.e., $L_2(Z^\beta)$), the expectations can be computed using

conditional distributions of the type $f^{z|\beta}(x|y) = f(x)[1 + \sum_{i=1}^{\infty} T_{ij}^{\alpha\beta} \chi_i(x) \chi_j(y)]$, $\alpha = 0, 1, \dots, N$; $\beta = 0, 1, 2, \dots, N$. The

conditional expectation, $E[\chi_l(Z^\alpha) | Z^\beta]$ is given by $E[\chi_l(Z^\alpha) | Z^\beta = y] = \int_{-\infty}^{\infty} \chi_l(x) f^{z|\beta}(x|y) dx = \int_{-\infty}^{\infty} \chi_l(x) f(x) \left[1 + \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} T_{ij}^{\alpha\beta} \chi_i(x) \chi_j(y) \right] dx = \sum_{j=1}^{\infty} T_{lj}^{\alpha\beta} \chi_j(Z^\beta)$.

The DK equations for $\chi_n^*(Z^0)$ are given by $E\left[\sum_{\alpha=1}^N \sum_{l=0}^{\infty} \lambda_{l\alpha}^{(n)} \chi_l(Z^\alpha) | Z^\beta\right] = E[\chi_n(Z^0) | Z^\beta]$, $\beta = 1, 2, \dots, N$ giving $\sum_{\alpha=1}^N \sum_{l=0}^{\infty} \lambda_{l\alpha}^{(n)} \sum_{j=1}^{\infty} T_{lj}^{\alpha\beta} \chi_j(Z^\beta) = \sum_{j=1}^{\infty} T_{nj}^{0\beta} \chi_j(Z^\beta)$, $\beta = 1, 2, \dots, N$.

Comparing coefficients of $\chi_j(Z^\beta)$, the DK equations reduce to $\sum_{\alpha=1}^N \sum_{l=0}^{\infty} \lambda_{l\alpha}^{(n)} T_{lj}^{\alpha\beta} = T_{nj}^{0\beta}$, $j = 1, 2, \dots$; $\beta = 1, 2, \dots, N$. In practice the summation over l is restricted to M terms. On examining these DK equations, it is clear that in the general case each $\chi_n(Z^0)$ is cokriged using $\chi_l(Z^\beta)$, $\beta = 1, 2, \dots, N$; $l = 0, 1, \dots, M$. The resulting cokriging matrix is the same as the simple cokriging matrix discussed in section “Cokriging” with $T_{lj}^{\alpha\beta} = \text{Cov}(\chi_l(Z^\alpha), \chi_j(Z^\beta))$. In the isofactorial case, due to the orthogonality of $(\chi_n(Z^\alpha), \chi_m(Z^\beta))$, $n \neq m$, $\alpha = 0, 1, \dots, N$; $\beta = 0, 1, \dots, N$, $T_{nm}^{\alpha\beta} = 0$, $n \neq m \quad \forall \alpha, \beta = 0, 1, \dots, N$. Thus, the simple cokriging matrix reduces to a block diagonal matrix with block diagonal matrices given by $\sum_{\alpha=1}^N \lambda_{n\alpha}^{(n)} T_{nj}^{\alpha\beta} = T_{nn}^{0\beta}$, $\beta = 1, 2, \dots, N$, for the n^{th} diagonal block. This means that the projection of $\chi_n(Z^0)$ onto ζ_D reduces to its simple kriging using only the $\chi_l(Z^\beta)$, $l = 0, 1, \dots, M$. It is therefore advantageous to use bivariate distributions that have an isofactorial form. More details on disjunctive kriging can be found in Matheron (1976a) and Armstrong and Matheron (1986).

In many applications an estimate of the “local conditional distribution,” $F(Z^0 | Z^1, Z^2, \dots, Z^N) \equiv F(Z^0 | N)$, say is obtained by taking $g(Z^0)$ to be the indicator function $I_{Z^0 \leq z} = \begin{cases} 1 & \text{if } Z^0 < z \\ 0, & \text{otherwise} \end{cases}$ and writing it as $I_{Z^0 \leq z} = \sum_{n=0}^M a_n \chi_n(Z^0)$.

Some of the important bivariate distributions that have isofactorial representations with polynomial factors are the bivariate Gaussian, bivariate Gamma, and bivariate negative binomial. More details of these and other models can be found in Matheron (1989) and Chiles and Delfiner (2012). To use these models the bivariate distribution is specified a priori and transformation of data such that at each location the random variable has the required marginal needed along with the assumption that each bivariate pair has the specified bivariate distribution. In the discrete case, the discrete diffusion

isofactorial model (Matheron 1984c; Lajaunie and Lantuejoul 1989) and the orthogonal indicator residual model (Rivoirard 1989, 1994) provide methods to develop isofactorial models based on factors that are obtained from the raw data. Broadly, the isofactorial models can also be classified into diffusion-type (e.g., bivariate Gaussian and bivariate gamma) called “models with edge effect” and other models that are called “models without edge effect” (Rivoirard 1994). In diffusion-type models (i.e., models without edge effect), between any two values in the regionalization there must exist all other intermediate values. On the other hand, in models without edge effect (such as the mosaic model and the orthogonal indicator residual model), the random function remains constant or fairly constant in small regions and varies abruptly across these. It is conceptualized that the random function can be realized over an underlying tessellation of tiles (or mosaics) wherein across tiles random variables do not show correlation whereas within tiles they may be constant, as in the mosaic model, or vary with a specified covariance structure from the centre to the edge, as in the orthogonal indicator residual model. The mosaic model is one in which corregionalized random variables show intrinsic correlation whereby cokriging reduces to kriging. Hence, for example, random functions that are modeled using the mosaic model justify replacing indicator-cokriging with indicator kriging (Matheron 1982).

Reducing the cokriging of components of a random vector $\mathbf{Z}(x) = (Z_1(x), Z_2(x), \dots, Z_p(x))^T$ to kriging of each of its components $Z_i(x)$, $i = 1, 2, \dots, p$ requires spatial orthogonality of the process $\mathbf{Z}$, that is, $\text{Cov}(Z_i(x), Z_j(x + \vec{h})) = 0$, $\forall x, \vec{h}, i \neq j$. Under the assumption of stationarity, methods such as principal components give transformations for orthogonality at $\|\vec{h}\| = 0$. The same transformation will not generally result in spatial orthogonality. Methods such as indicator principal component kriging assume that correlation between principal components is small for small values of $\|\vec{h}\|$. The problem is to obtain a transform $\mathbf{Y} = \mathbf{AZ}$ such that $\mathbf{AC}(\vec{h})\mathbf{A}^T = \mathbf{D}$ where $\mathbf{D}$ is a diagonal matrix for all $\vec{h}$. This is the problem of simultaneous diagonalization of the family of matrices $\mathbf{C}(\vec{h})$. Subramanyam and Pandalai (2001, 2004) give conditions under which this is possible. For models such as the linear model of corregionalization where $\mathbf{C}(\vec{h}) = \sum_{l=1}^K \mathbf{B}_l c^l(\vec{h})$, it is necessary that the matrices $\mathbf{B}_1, \mathbf{B}_2, \dots, \mathbf{B}_k$ form a commuting family of matrices so that simultaneous diagonalization is possible. When $k = 1$, that is, the intrinsic model, this condition is always met. Switzer and Green (1984) and Green et al. (1988) have shown that a two-stage rotation procedure always achieves spatial orthogonality. The factors obtained by this procedure are

called MIN/MAF autocorrelation factors. Details of the procedure as applied in geostatistics can be found in Vargas-Guzmán and Dimitrakopoulos (2003). The technique therefore allows building models where transforms of indicator functions with covariance models such as LMC where $k = 2$ are spatially orthogonal and hence give a general model for constructing isofactorial models (Rivoirard et al. 2014).

There are situations where certain covariance structures such as the Markov models (Journel 1999) along with specific data configurations result in reduction of cokriging systems to kriging Subramanyam and Pandalai (2008).

Disjunctive Kriging in the Bivariate Gaussian Model

The bivariate Gaussian distribution of random variables X and Y given by $g(x, y)$ can be written as $g(x, y) =$

$g(x)g(y) \left[1 + \sum_{n=1}^{\infty} \frac{\rho^n}{n!} H_n(x)H_n(y) \right]$, where $g(x)$, $g(y)$ are $N(0, 1)$ densities, $\rho = \text{Cov}(X, Y)$, $\rho^n/n! = \text{Cov}(H_n(X), H_n(Y))$ with $H_n(x)$ and $H_n(y)$ being the n^{th} Hermite polynomials given by $H_n(x) = \frac{1}{g(x)} \frac{\partial^n g(x)}{\partial x^n}$ and $H_n(y) = \frac{1}{g(y)} \frac{\partial^n g(y)}{\partial y^n}$. The Hermite polynomials are orthogonal polynomials with $H_0(X) = 1$, $E[H_n(X)] = 0$, and $\text{Var}(H_n(X)) = n!$, $n = 1, 2, \dots$. Thus $\frac{H_n(X)}{\sqrt{n!}} = \eta_n(X)$, say $n = 0, 1, \dots$, are orthonormal polynomials.

If $Z(x) = \varphi(Y(x))$, where $Y(x)$ is $N(0, 1)$ and if it is assumed that $(Y(x), Y(x + \vec{h}))$ are standard bivariate normal, that is, $N(0, 0, 1, 1, \rho_h)$, then the process Y is a bivariate Gaussian process. The bivariate density of all pairs of random variables $(Y(x), Y(x + \vec{h}))$ is isofactorial with $g(y(x), y(x + \vec{h})) = g(y(x))g(y(x + \vec{h})) \left[1 + \sum_{n=1}^{\infty} \frac{\rho_h^n}{n!} H_n(y(x))H_n(y(x + \vec{h})) \right]$. The DK-equations for H_n^* are given by $\sum_{\alpha=1}^N \lambda_{n\alpha} \rho_{\alpha\beta}^n = \rho_{0\beta}^n$, $\beta = 1, 2, \dots, N$.

From the observed data the transformation to $y(x)$ is obtained using the normal-score transform, that is, $y(x) = G^{-1}\hat{F}(z(x))$, where $\hat{F}(z)$ is the empirical distribution function of the observations on Z and G is the distribution function of the standard Gaussian random variable. The monotone function ϕ that gives $Z(x) = \phi(Y(x))$ where $\phi(Y(x)) = \sum_{n=0}^{\infty} \frac{a_n}{n!} H_n(Y(x))$ with $a_n = \int_{-\infty}^{\infty} \phi(y) H_n(y) g(y) dy$ is known in geostatistics as the *anamorphosis function*. The covariance function is modeled using the experimental covariance function of the transformed data or computed from the modeled covariance function of Z since $\text{Cov}(Z(x), Z(x + \vec{h})) = \text{Cov}(\phi(Y(x)), \phi(Y(x + \vec{h}))) = \sum_{n=1}^{\infty} \frac{a_n^2}{n!} \rho_h^n$.

Change of Support

Observations $z(x)$ on the random process Z at the location x are generally averages over small volumes centered at x . Averages $Z_v(x) = \frac{1}{|v|} \int_{v(x)} Z(x) dx$ of Z over volumes v centered at x are often required to be estimated (or simulated). The volume v over which the random function Z is averaged to get $Z_v(x)$ is called the *support* of the random variable $Z_v(x)$. If $Z(x)$ is taken at the point x only, it is called a *point-support* random variable. The probability distribution of $Z_v = \{Z_v(x), x \in D\}$ cannot be modeled as there are no observations on Z_v . Calculation of the probability distribution of Z_v requires all the finite-dimensional distributions of Z , which are usually not available. Hence, models for the probability distribution of Z_v need to be developed. This is referred to as the *global change of support problem*. In many estimation (and simulation) procedures, the conditional distribution of $Z_v(x_0) | Z(x_\alpha)$, $\alpha = 1, 2, \dots, N$ also needs to be specified. This is called the *local change of support problem*. Global and local change of support problems are important problems in geostatistics.

An early solution to the global change of support problem was based on the hypothesis of the *law of permanence of distributions*. Here it is assumed that the standardized probability distribution of Z_v is the same as that of Z , that is, $\frac{Z_v - m_v}{\sigma_v} \sim \frac{Z - m}{\sigma}$, where $E[Z_v] = m_v$, $E[Z] = m$, $\text{Var}(Z_v) = \sigma_v^2$ and $\text{Var}(Z) = \sigma^2$. When Z is a second-order stationary random function, $m_v = m$ and $\sigma_v^2 = \frac{1}{|v|^2} \int_v \int_v C(x - y) dx dy = \overline{C}(vv)$, say, which can be estimated using $C(\vec{h})$ representing the modeled covariance of Z which is available. Since $\frac{Z_v - m_v}{\sigma_v}$ and $\frac{Z - m}{\sigma}$ have identical distribution F , say, an estimate F^* of the distribution function of Z leads to an estimate F_v^* , the distribution function of Z_v , that is, $F_v^*(z) = F^*\left(m + \frac{\sigma}{\sigma_v}(z - m)\right)$. The global estimate $\psi^*(Z_v)$ of any function $\psi(Z_v)$ is then given by $\int_{-\infty}^{\infty} \psi(u) F_v^*(u) du$.

The problem of estimating the local conditional distribution $F_v(x; z | N) = \text{Prob}[Z_v(x) \leq z | (Z(x_\alpha) = z(x_\alpha), \alpha = 1, 2, \dots, N)]$ is achieved by post-kriging modification of $F^*(x; z | N)$.

The *affine change of support* model relies upon the “hypothesis of permanence” and the first two moments of the marginal distributions of $Z_v(x)$ and $Z(x)$ and hence a more general model is desirable for better estimation of random variables with a different support than that of the observed data. One of the important models that is used for addressing the change of support problem is known as Cartier’s relation after Matheron (1984a, b) who introduced this model for (additive) random variables that are averages of point-support random variables. This model uses the notion of a randomly chosen point $\tilde{x}$ within a volume v . Let $Z(\tilde{x})$ be the random variable associated with the randomly chosen

point $\tilde{x}$. The expected value of $Z(\tilde{x})$ is given by $E[Z(\tilde{x})] = \frac{1}{|v|} \int_{v(x)} Z(u) du = Z_v(x)$ where $Z_v(x)$ is the random variable associated with the volume v centered at x . It is now assumed that $E[Z(\tilde{x}) | Z_v(x)] = Z_v(x)$. Due to the assumption of stationarity, $E[Z(\tilde{x}) | Z_v] = Z_v$. This assumption is called *Cartier's relation*. A consequence of this is that $Var(Z_v) = \sigma_v^2 < Var(Z) = \sigma^2$. A similar relation, in respect of the grade $Z_v(\tilde{x})$ of a random block of volume v within a panel of volume V gives $E[Z_v(\tilde{x}) | Z_V(x)] = Z_V(x)$.

In mining geology, the problem of estimation of recovery functions, such as recoverable tonnage in blocks of volume v that are above specified cutoff grade, and the quantity of metal contained in such blocks has received much attention. In addition to the “*effect of support*” on the recovery functions, there is also an “*effect of information*” since selection of blocks is made on the basis of the estimated grades of these blocks and not on their true grades. This aspect has been addressed in local and global recovery estimation problems (Matheron 1976b; Marechal 1984) and led to the development of the selectivity of distributions (Matheron 1984b) which was emphasized by Matheron as the “second principle of geostatistics.”

As discussed earlier in section “*Disjunctive Kriging in the Bivariate Gaussian Model*” for the Gaussian case, it is convenient to assume $Z(x) = \phi(Y(x))$ and to choose a suitable model for the process Y which is assumed to be bivariate-stationary. This anamorphosis (transformation) function $\phi(Y(x))$ is written as before as $\phi(Y(x)) = \sum_{n=0}^{\infty} \psi_n \chi_n(Y(x))$ and in particular $Z(\tilde{x}) = \phi(Y(\tilde{x})) = \sum_{n=0}^{\infty} \psi_n \chi_n(Y(\tilde{x}))$. The Cartier's relation then gives $E[\phi(Y(\tilde{x})) | Y_v] = \phi_v(Y_v)$, where $Z_v = \phi_v(Y_v)$ with ϕ_v being the anamorphosis function for Z_v . The random variable $Z_v(x) = \frac{1}{|v|} \int_{v(x)} Z(x) dx$ can be written as $Z_v(x) = \phi_v(Y_v(x)) = \sum_{n=0}^{\infty} \theta_n \chi_n^v(Y_v(x))$ where χ_n^v , $n = 0, 1, 2, \dots$ form a basis for $L_2(Y_v(x))$ and $\theta_n = E[\phi_v(Y_v(x)) \chi_n^v(Y_v(x))]$.

To illustrate the method, assume that $Y(\tilde{x})$ and $Y_v(x)$ are standard bivariate Gaussian random variables of which the density can be written as $g(y(\tilde{x}), y_v(x)) = g(y(\tilde{x}))g(y_v(x)) \left[1 + \sum_{n=1}^{\infty} \frac{r_v^n}{n!} H_n(y(\tilde{x}))H_n(y_v(x)) \right]$ where $r_v^n = Cov(H_n(Y(\tilde{x})), H_n(Y_v(x)))$ and $\tilde{x}$ is a randomly chosen point in $v(x)$, the support of $Y_v(x)$. (Bivariate density functions such as the one above that describe the joint behavior of random variables on point and block support are called *point-block models*. In the case of bivariate Gaussian density, this model is known as the *discrete Gaussian model*.) This gives ϕ_v

$$(Y_v(x)) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x)) = \sum_{n=0}^{\infty} \frac{a_n}{n!} H_n(Y(\tilde{x})) | Y_v(x) = \sum_{n=0}^{\infty}$$

$\frac{a_n}{n!} r_v^n H_n(Y_v(x))$, where $a_n = E[\phi(Y(x)) H_n(Y(x))]$, and $b_n = E[\phi_v(Y_v(x)) H_n(Y_v(x))] = a_n r_v^n$. Under stationarity, $\phi_v(Y_v) = \sum_{n=0}^{\infty} \frac{a_n}{n!} r_v^n H_n(Y_v)$. Using the relation $Var(Z_v(x)) = Var(\phi_v(Y_v(x))) = \sum_{n=0}^{\infty} \frac{a_n^2}{n!} r_v^{2n}$, the value of r_v can be estimated from data since $Var(Z_v(x)) = \frac{1}{|v|} \int_{v(x)} \int_{v(x)} C(y-y') dy dy' = \overline{C}(vv)$ which can be computed from the modeled variogram of Z . For details of change of support in isofactorial models one may see Matheron (1984a).

Since ϕ_v is identified, $P[Z_v \leq z]$ is given by $P[\phi_v(Y_v) \leq z] = P[Y_v \leq \phi^{-1}(z)]$, which resolves the problem of global change of support since the distribution function of Z_v is specified.

For local estimation, the conditional distribution of $Z_v(x_0) | (Z(x_\alpha), \alpha = 1, 2, \dots, N)$ is required. In general, estimates of $g(Z_v(x_0)) | (Z(x_\alpha), \alpha = 1, 2, \dots, N)$ may be required, where $g(Z_v(x_0)) = h\left(Y_v(x_0) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_0))\right)$ with $b_n = E[h(Y_v(x_0)) H_n(Y_v(x_0))]$. In disjunctive kriging, the projection $g(Z_v(x_0))^*$ of functions $g(Z_v(x_0))$ of $Z_v(x_0)$ onto ζ_D (the vector-space generated by all single variable functions of $Z(x_\alpha), \alpha = 1, 2, \dots, N$) is considered. This is characterized by $E[g(Z_v(x_0))^* | Z(x_\alpha)] = E[g(Z_v(x_0)) | Z(x_\alpha)], \alpha = 1, 2, \dots, N$, where $g(Z_v(x_0))^* = \sum_{\alpha=1}^N \Lambda_\alpha(Z(x_\alpha))$. As before the estimate

$g(Z_v(x_0))^*$ is given by $g(Z_v(x_0))^* = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n^*(Y_v(x_0))$ where $H_n^*(Y_v(x_0))$ is obtained as the solution of DK equations characterized by $E[H_n^*(Y_v(x_0)) | Y(x_\alpha)] = E[H_n(Y_v(x_0)) | Y(x_\alpha)], \alpha = 1, 2, \dots, N$. This gives the DK equations $\sum_{\beta=1}^N \lambda_{n\beta}^{(n)} \rho_{\alpha\beta}^n = \rho_{v\alpha}^n, \alpha = 1, 2, \dots, N$, where $\rho_{v\alpha} = Cov(Y_v(x_0), Y(x_\alpha))$ can be estimated from data as $Cov(Z_v(x_0), Z(x_\alpha)) = \frac{1}{|v|} \int_{v(x)} C(y, \alpha) dy = \overline{C}(v, \alpha) = \sum_{n=0}^{\infty} \frac{a_n^2}{n!} r_v^n \rho_{v\alpha}^n$.

Since $H_n(Y_v(x))$ is estimated, the estimate of any function $g(Z_v(x_0)) = h\left(Y_v(x_0) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_0))\right)$ is obtained as $g(Z_v(x_0))^* = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_0))^*$ (approximated in practice by $g(Z_v(x_0))^* = \sum_{n=0}^M \frac{b_n}{n!} H_n(Y_v(x_0))^*$ where M is chosen suitably). In particular, the conditional expectations, $E[I_{Z_v(x_0) \leq z}(x_0) | (Z(x_\alpha), \alpha = 1, 2, \dots, N)]$ and $E[Z_v(x_0) I_{Z_v(x_0) \leq z}(x_0) | (Z(x_\alpha), \alpha = 1, 2, \dots, N)]$ are important in some applications in mining geology.

In many mining problems, larger panels of volume V may be divided into N smaller blocks of volume v . As before, writing $Z_v(x) = \phi_v(Y_v(x))$ and developing in terms of Hermite polynomials gives $\phi_v(Y_v(x)) = \sum_{n=0}^{\infty} \frac{a_n}{n!} r_v^n H_n(Y_v(x))$ where the

a_n 's are coefficients as given previously and $r_v^n n! = \text{Cov}(H_n(Y(\tilde{x})), H_n(Y_v(x)))$. It may be required to estimate recovery functions $\frac{1}{N} \sum_{i=1}^N \psi(Z_v(x_i))$ of N small blocks of volume v centered at x_i within larger panels of volume V centered at x . Writing $\psi(Z_v(x)) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x))$ where $b_n = E[\psi(Z_v(x)) H_n(Y_v(x))]$, the function required to be estimated is $\frac{1}{N} \sum_{i=1}^N \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_i)) = \sum_{n=0}^{\infty} \frac{b_n}{n!} \cdot \left(\frac{1}{N} \sum_{i=1}^N H_n(Y_v(x_i)) \right)$. This problem of local estimation can be tackled by DK by writing $E \left[\frac{1}{N} \sum_{i=1}^N H_n(Y_v(x_i)) | Y(x_\alpha) \right] = \frac{1}{N} \sum_{i=1}^N \rho^n(v_i, \alpha)$ where $\rho(v_i, \alpha) = \text{Cov}(Y_i(x_i), Y(x_\alpha))$. The DK estimate $\left(\frac{1}{N} \sum_{i=1}^N H_n(Y_v(x_i)) \right)^{DK} = \left(\frac{1}{N} \sum_{i=1}^N H_n(Y_v(x_i)) \right)$ is obtained by solving the DK equations $\sum_{\alpha=1}^N \lambda_{n\alpha} \rho_{n\alpha}^n = \frac{1}{N} \sum_{i=1}^N \rho^n(v_i, \beta)$, $\beta = 1, 2, \dots, N$.

Another problem is to estimate $E \left[\frac{1}{N} \sum_{i=1}^N \psi(Z_v(x_i)) | Z_V(x) \right]$, where $Z_V(x)$ is the grade of the panel of volume V centered at x written as $Z_V(x) = \phi_V(Y_V(x)) = \sum_{n=0}^{\infty} \frac{a_n}{n!} r_V^n H_n(Y_V(x))$ where r_V is obtained from $\text{Var}(Z_V(x))$ as explained previously and $Z_v(x) = \sum_{n=0}^{\infty} \frac{a_n}{n!} r_v^n H_n(Y_v(x))$. Under the discrete Gaussian model, the quantity to be estimated can be written as the conditional expectation, $E[\psi(Z_v(\tilde{x}) | Z_V(x))]$, where $Z_v(\tilde{x})$ is a random block of volume v within the panel of volume $V(x)$. The expected value $E[\psi(Z_v(\tilde{x}) | Z_V(x))]$ can be written as $E[\psi'(Y_v(\tilde{x}) | Y_V(x))]$, where $\psi'(Y_v(\tilde{x})) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(\tilde{x}))$ with $b_n = E[\psi(Z_v(\tilde{x})) H_n(Y_v(\tilde{x}))]$. Since $E[Z_v(\tilde{x}) | Z_V(x)] = Z_v(x)$ this gives $E[H_n(Y_v(\tilde{x}) | Y_V(x))] = \left(\frac{r_v}{r_V} \right)^n$ and thus, $E[\psi'(Y_v(\tilde{x}) | Y_V(x))] = E \left[\sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(\tilde{x})) | Y_V(x) \right] = \sum_{n=0}^{\infty} \frac{b_n}{n!} \left(\frac{r_v}{r_V} \right)^n H_n(Y_V(x))$. Since $Z_V(x)$ is unknown, one of the ways in which this problem is often tackled is by making the approximation that $Z_V^*(x)$ representing the estimate of $Z_V(x)$ can be written as $Z_V^*(x) = \sum_{n=0}^{\infty} \frac{a_n}{n!} r_V^n H_n(Y_V^*(x))$. This is an approximation since $Y_V^*(x) = \phi_V^{-1}(Z_V^*(x))$ is not $N(0, 1)$. The approximation gives $E[\psi'(Y_v(\tilde{x}) | Y_V(x))] \approx \sum_{n=0}^{\infty} \frac{b_n}{n!} \left(\frac{r_v}{r_V} \right)^n H_n(Y_V^*(x))$. This method of local recovery estimation is called the method of *uniform conditioning*. Here the estimate $Z_V^*(x)$ can be obtained by any procedure such as ordinary kriging and hence is useful in situations where local stationarity can be assumed (see, e.g., Guibal and Remacre 1984). Other more exact methods of uniform conditioning to

estimate $E \left[\frac{1}{N} \sum_{i=1}^N \psi(Z_v(x_i)) | Z_V^*(x) \right]$ can be developed with the estimate $Y_V^*(x) = \sum_{\alpha=1}^K \lambda_\alpha Y(x_\alpha)$, where $Y(x_\alpha)$, $\alpha = 1, 2, \dots, K$, are the Gaussian transforms at data locations, but these methods rely on stronger assumptions of stationarity.

Other bivariate distributions with isofactorial representations (such as the bi-gamma, bivariate negative binomial, and other models, such as the orthogonal residual model and the discrete isofactorial models) also admit valid change of support models (Matheron 1989). Other change of support models, such as the mosaic change of support model (different from the mosaic model for a random function), have also been studied for specific applications (Matheron 1984d).

Another approach is the multi-Gaussian approach (see, e.g., Verly 1983; Rivoirard 1994). Here, the random variables $Y_v(x_0), Y(x_1), Y(x_2), \dots, Y(x_N)$ are multivariate Gaussian with the conditional distribution $g(Y_v(x_0) | (Y(x_\alpha) = y(x_\alpha), \alpha = 1, 2, \dots, N)) \sim N(y_v^{SK}(x_0), \sigma_{SK}^2(x_0))$, where $y_v^{SK}(x_0)$ and $\sigma_{SK}^2(x_0)$ are the simple kriging and variance of simple kriging, respectively, of $Y_v(x_0)$. Estimation or change of support problems involving functions $\psi(Z_v(x_0)) = h(Y_v(x_0) = \sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_0)))$ reduce to that of specifying $g(Y_v(x_0) | (Y(x_\alpha), \alpha = 1, 2, \dots, N))$ where $Y(x_\alpha) = \phi^{-1}(Z(x_\alpha))$ with ϕ being the anamorphosis function for the point-support random variables. This gives $\psi(Z_v(x_0))^* = E[h(Y_v(x_0) | Y(x_\alpha), \alpha = 1, 2, \dots, N)] = \int_{-\infty}^{\infty} h(u) g(u | (y(x_\alpha), \alpha = 1, 2, \dots, N)) d(u)$. Another equivalent way to obtain the estimate $\psi(Z_v(x_0))^* = E[h(Y_v(x_0) | Y(x_\alpha), \alpha = 1, 2, \dots, N)]$ is to evaluate it by using the development of $h(Y_v(x_0))$ in terms of Hermite polynomials. Writing $Y_v(x_0) | (Y(x_\alpha), \alpha = 1, 2, \dots, N) = (y_v^{SK}(x_0) + \sigma_{SK}(x_0)U)$, where U is uniform $[0, 1]$, the estimate is given by $\psi(Z_v(x_0))^* = E \left[\sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(y_v^{SK}(x_0) + \sigma_{SK}(x_0)U) \right] = E \left[\sum_{n=0}^{\infty} \frac{b_n}{n!} H_n(Y_v(x_0)) | \frac{Y_v^{SK}(x_0)}{S} \right] = \sum_{n=0}^{\infty} \frac{b_n}{n!} E \left[H_n(Y_v(x_0)) | \frac{Y_v^{SK}(x_0)}{S} \right] = \sum_{n=0}^{\infty} \frac{b_n}{n!} S^n H_n \left(\frac{Y_v^{SK}(x_0)}{S} \right)$, where $S^2 = \text{Var}(Y_v^{SK}(x_0))$. When $Y(x_\alpha) = y(x_\alpha)$, $\alpha = 1, 2, \dots, N$, $E[h(Y_v(x_0) | Y(x_\alpha) = y(x_\alpha), \alpha = 1, 2, \dots, N)] = \sum_{n=0}^{\infty} \frac{b_n}{n!} S^n H_n \left(\frac{Y_v^{SK}(x_0)}{s} \right)$ with $s = \sum_{\alpha=1}^N \lambda_\alpha^{SK} C_Y(x_\alpha, v)$, where $C_Y(\frac{-}{h})$ is the model of the covariance function of Y .

This section should be regarded as an overview of the principle of change of support. Specific applications may require appropriate adaptation of the preceding principles.

Simulation

Natural phenomena are often complex and details of complexity vary with the scale of observation. Complex patterns are formed due to the interaction of several processes that operate independently, often at different scales. Smooth patterns that are sometimes observed at one scale become rough at other smaller scales of observation. Discerning and describing such patterns depends on the density of data and the scale at which description is desired. Information that may be available may include measurements and categorizations of observations, called *hard-data*, or other empirical information such as bounds on possible values (such as bounds on rainfall data in a region), expert opinions, order-relations (such as probable order of successions of strata in a terrain), and other subjective information that are collectively termed *soft-data*. It is of interest to make informed inferences on patterns that can be discerned from hard and soft data available on natural phenomena to make use of them to produce possible maps with desired density of detail that display patterns akin to those observed in reality.

Discerning patterns in natural phenomena on the basis of hard data can be done using deterministic or probabilistic methods. Due to lack of complete information or understanding of natural phenomena, and due to inherent randomness in many natural processes, deterministic methods often have limited success in modeling the true map of natural processes. Probabilistic methods attempt to overcome some of the lacunae by using models that try to capture the nature and form of randomness in natural processes. In the probabilistic approach, natural phenomena are considered as random processes with data being observations on them. The description of the process is defined by modeling the joint distribution of the collection of random variables that constitute the random process by parametrizing the model and estimating parameters from observed data. In practice, various assumptions of homogeneity (stationarity) are invoked to reduce the modeling to second-order moments involving covariances which are defined through pairs of random variables (and hence termed *two-point statistics*). This approach is useful when the phenomena under study exhibit a degree of homogeneity at the desired scale. An example is the likely homogeneity of reflectances in pixels in specific bands of the electromagnetic spectrum over the canopy of a featureless forested terrain. On the other hand, if the terrain has topographic features and includes forested terrains plus braided and meandering streams with fluvial sand bars and wash-over flats, modeling the observed satellite or areal image over any band of the spectrum becomes complicated. Another example of a complicated reality could be the problem of modeling average grades of ore in volumes of rock where the orebody consists of a randomly branching system of veins. Probabilistic methods based on two-point statistics may become incapable

of capturing the true nature of a natural process at some desired scale as the process becomes more and more complex. The performance of probabilistic methods may be enhanced by considering *multi-point statistics* such as data-driven models of joint distributions. For example, in porous strata, the characteristic of interest could be the connectedness of pores of a minimum size. Such problems could be addressed by examining expected values of the product of indicators at multiple locations separated by a vector $\vec{h}$.

In the estimation problem dealt with in previous sections, the objective is to obtain optimal values of the random process Z at unobserved locations $s_1, s_2, \dots, s_M$, say, based on observations on Z at locations $x_1, x_2, \dots, x_N$ wherein optimization is performed by minimizing $\text{Var}(Z(s_i) - Z^*(s_i))$ at location s_i , where $Z^*(s_i)$ is a suitable estimator of the unknown $Z(s_i)$. The optimization results in *smoothing*, that is, the predicted values are less dispersed than the actual values. A consequence of this is that the inherent variability of the random process Z is not reproduced in the set of predicted values, and moreover, the patterns or features that are characteristic of Z may not be manifested in the map of estimated values.

An alternative is to remove the smoothing effect on the predicted map of Z by perturbing or roughening it while trying to retain essential features that characterize the random phenomenon. This process is called *simulation*. There are many techniques that have been explored for performing simulations of random processes. If T denotes hard and soft data on the random process Z , simulation can be considered as a mapping $M : T \rightarrow S$ where S is the set of possible maps. Simulation which uses only hard data is discussed first in the sequel and is followed by methods that use both hard data and soft information. Object-based simulation techniques fall at the opposite end of the spectrum and place emphasis on reproduction of geometries of geological objects along with their lateral and vertical successions. In the sequel some simulation techniques are discussed in detail and a summary of some of the other techniques is provided at the end.

Simulation of a Second-Order Stationary Process

Let $Z = \{Z(x) \in D\}$ be a random process characterized by the collection of all k -variate distribution functions $F^{(k)}$ for $k = 1, 2, \dots$ and all possible choice of support points $x \in D$. Let $s_1, s_2, \dots, s_M$ be locations of interest at which Z is not observed and let $F^{(M)} = F_{Z(s_1), Z(s_2), \dots, Z(s_M)}$ be the M -variate joint distribution of $Z(s_1), Z(s_2), \dots, Z(s_M)$. A realization $z^s(s_1), z^s(s_2), \dots, z^s(s_M)$ of Z at $s_1, s_2, \dots, s_M$ generated from $F^{(M)}$ is said to be a *non-conditional simulation* $Z^{(NS)}$ of Z at $s_1, s_2, \dots, s_M$. If $F^{(N+M)} = F_{Z(s_1), Z(s_2), \dots, Z(s_M), Z(x_1), Z(x_2), \dots, Z(x_N)}$ is the joint distribution of $Z(s_1), Z(s_2), \dots, Z(s_M), Z(x_1), Z(x_2), \dots, Z(x_N)$ and $z(x_1), z(x_2), \dots, z(x_N)$ are observations on the random variables

$Z(x_1), Z(x_2), \dots, Z(x_N)$, then a realization $z^s(s_1), z^s(s_2), \dots, z^s(s_M), z(x_1), z(x_2), \dots, z(x_N)$ generated from the joint distribution $F^{(M+N)}$ is said to be a *conditional simulation* $Z^{(CS)}$ of Z at $s_1, s_2, \dots, s_M$. At any location $s \in D$, the random variable $Z(s)$ can be written as $Z(s) = Z^*(s) + (Z(s) - Z^*(s))$ where $Z^*(s)$ is an estimate of $Z(s)$ and $Z(s) - Z^*(s)$ is called error. If the error is replaced by an error $(Z^{(NS)}(s) - Z^{(NS)*}(s))$ called *isomorphous error* using a non-conditional simulation $Z^{(NS)}$ at $s_1, s_2, \dots, s_M, x_1, x_2, \dots, x_N$ from the joint distribution $F^{(M+N)}$, independent of the data at $x_1, x_2, \dots, x_N$, where $Z^{(NS)*}(s)$ is the estimate of $Z^{(NS)}(s)$ using $Z^{(NS)}(x_1), Z^{(NS)}(x_2), \dots, Z^{(NS)}(x_N)$, then $Z^{(CS)}(s) = Z^*(s) + (Z^{(NS)}(s) - Z^{(NS)*}(s))$ with $Z^{(CS)}(x)$ being the conditional simulation of Z at s . Many simulation methods build isomorphous error through various techniques specific to them.

If $\mathbf{Z} = \{Z(x), x \in D\}$, where $\mathbf{Z}(x)$ is a p -dimensional random vector, then the conditional simulation $\mathbf{Z}^{(CS)}(s)$ or non-conditional simulation $\mathbf{Z}^{(NS)}(s)$, at location s , can be generated by simultaneously simulating components of $\mathbf{Z}(s)$. Such simulation is called *co-simulation*. Co-simulation may often use cokriging as an intermediate step in the procedure.

Similarly, if $\mathbf{Y} = \Psi(\mathbf{Z})$, then conditional or non-conditional simulations $\mathbf{Y}^S$ of $\mathbf{Y}$ at $s_1, s_2, \dots, s_M$ can be built from appropriate joint distributions. If Ψ is the indicator function $(I_{Z(x) < z_j}, j = 1, 2, \dots, p)^T$, then co-simulation of the p -variate random function $\mathbf{Y}$ is called *indicator co-simulation*. If each component of $\mathbf{Y}$ is simulated independently using only information on that component, then the simulation is called *indicator simulation*.

Let $\mathbf{C}_{11}$ be the covariance matrix of $\mathbf{Z}^D = (Z(x_1), Z(x_2), \dots, Z(x_N))^T$, $\mathbf{C}_{22}$ that of $\mathbf{Z}^G = (Z(s_1), Z(s_2), \dots, Z(s_M))^T$ and $\mathbf{C}_{12}$ the matrix of cross-covariances and let $\mathbf{C} =$

$$\begin{bmatrix} \mathbf{C}_{11} & \mathbf{C}_{12} \\ \mathbf{C}_{21} & \mathbf{C}_{22} \end{bmatrix} \text{ be the covariance matrix of } \mathbf{Z} = [\mathbf{Z}^D \ \mathbf{Z}^G]^T.$$

Let $\mathbf{L}$ be such that $\mathbf{LL}^T = \mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12}$. Let $\mathbf{Z}^S = (Z^s(s_1), Z^s(s_2), \dots, Z^s(s_M))^T$ and let $\mathbf{Z}^S = \mathbf{Z}_s^* + \mathbf{LW}$ where $\mathbf{W} = (W_1, W_2, \dots, W_M)^T$ is a vector of independent random variables with mean $\mathbf{0}$ and variance $\mathbf{1}$ and $\mathbf{Z}_s^* = (Z^*(s_1), Z^*(s_2), \dots, Z^*(s_M))^T$ is the vector of kriged estimates of $\mathbf{Z}^G = (Z(s_1), Z(s_2), \dots, Z(s_M))^T$. If Z is a second-order stationary process, $(z(x_1), z(x_2), \dots, z(x_N), z^s(s_1), z^s(s_2), \dots, z^s(s_M))^T$ is a realization of a second-order stationary process with the covariance structure $\mathbf{C}$. This process of obtaining $\mathbf{Z}^S$ is a method of simulating the random process Z at locations $s_1, s_2, \dots, s_M$. If Z is assumed to be a Gaussian process and $W_1, W_2, \dots, W_M$ are independent $N(0, 1)$ random variables, the realization $(z(x_1), z(x_2), \dots, z(x_N), z^s(s_1), z^s(s_2), \dots, z^s(s_M))^T$ is a realization from the joint distribution of $\mathbf{Z} = [\mathbf{Z}^D \ \mathbf{Z}^G]^T$ which is multi-Gaussian. In this case $\mathbf{LL}^T$ is the covariance matrix of

$\mathbf{Z}^G | \mathbf{Z}^D$ and $\mathbf{z}^S$ is a realization from this conditional distribution. For this reason, the matrix $\mathbf{LL}^T$ is called the *conditional covariance matrix*.

Sequential Gaussian Simulation

A node-by-node implementation of the procedure detailed in the previous section results in a simulation technique known as the *Sequential Gaussian Simulation*. As before, let the random process Z be observed at $x_1, x_2, \dots, x_N$ and let $Z(x) = \phi(Y(x))$, $x \in D$ and let $Y(x) \sim N(0, 1)$, $x \in D$, where ϕ is a suitable anamorphosis function as discussed previously. If in addition, it is assumed that Y is a Gaussian process, $Y = \phi^{-1}(Z)$ has covariance matrix

$$\mathbf{C}_Y = \begin{bmatrix} \mathbf{C}_{11}^Y & \mathbf{C}_{12}^Y \\ \mathbf{C}_{21}^Y & \mathbf{C}_{22}^Y \end{bmatrix}. \text{ Sequential Gaussian simulation proceeds}$$

by defining a random path through locations that are to be simulated. Now let $s_1, s_2, \dots, s_M$ be that ordered path of locations to be simulated. Let s_i be the node to be simulated at the i^{th} step of the procedure. The simulated value is $z^S(s_i) = \phi(y^S(s_i))$ where $y^S(s_i) = y_{SK}^*(s_i) + \sigma_{SK}u$ with $y_{SK}^*(s_i)$ being the simple kriging of $y(s_i)$. The kriging is done with $y(x_1), y(x_2), \dots, y(x_N), y^s(s_1), y^s(s_2), \dots, y^s(s_{i-1})$, the N data $(y(x_1), y(x_2), \dots, y(x_N))^T = \mathbf{y}^D$, say, and the $i-1$ previously simulated values. The corresponding variance of estimation by simple kriging is given by $\sigma_{SK}^2(s_i)$ and u is independently drawn from $N(0, 1)$. The simulated value $y^S(s_i)$ at the i^{th} step is a realization of the random variable $Y^S(s_i) = y_{SK}^*(s_i) + \sigma_{SK}U$ where $y_{SK}^*(s_i) = E[Y(s_i) | \mathbf{y}^D, y^s(s_1), y^s(s_2), \dots, y^s(s_{i-1})]$ and $\sigma_{SK}^2(s_i)$ is the variance of $Y(s_i) | \mathbf{y}^D, y^s(s_1), y^s(s_2), \dots, y^s(s_{i-1})$. It can be shown that $y(x_1), y(x_2), \dots, y(x_N), y^s(s_1), y^s(s_2), \dots, y^s(s_M)$ is a realization from the process Y . This gives $\mathbf{Z}^S = \phi(\mathbf{Y}^S)$. At the i^{th} step of sequential Gaussian simulation, $y(s_i)$ is the realization of $Y(s_i)$ with conditional distribution $f(y(s_i) | \mathbf{y}^D, y(s_1), y(s_2), \dots, y(s_{i-1}))$. On completion of simulation, $y(x_1), y(x_2), \dots, y(x_N), y(s_1), y(s_2), \dots, y(s_M)$ is a realization from the required joint probability function $f(y(x_1), y(x_2), \dots, y(x_N), y(s_1), y(s_2), \dots, y(s_M))$ which is obtained as the product $f(\mathbf{y}^D) \cdot f(y(s_1) | \mathbf{y}^D) \cdot f(y(s_2) | \mathbf{y}^D, y(s_1)) \cdot \dots \cdot f(y(s_M) | \mathbf{y}^D, y(s_1), \dots, y(s_{M-1}))$ since at each step, u is generated from independent $N(0, 1)$ distributions.

Sequential Indicator Simulation

A non-parametric method of simulation that has found wide application is that of *Sequential Indicator Simulation* (Journel and Alabert 1988). Here, at each location s where it is required to simulate the random field Z , an estimate $\hat{F}_{Z(s)}(z|N)$ given by $\hat{F}_{Z(s)}(z|N) = E[I_{Z(s) \leq z} | N]$ (i.e., the kriged value of $I_{Z(s) \leq z}$ at location s as discussed previously in section “Non-Parametric Estimation: Multiple Indicator Kriging”). A value $z^s(s)$ is drawn from $\hat{F}_{Z(s)}(z|N)$. To simulate the next point along a random path through the set $\{s\}$ of all points

where simulation is desired, the process is repeated with the newly generated $z^s(s)$ included as part of data.

Simulation by Matrix Decomposition

When M and N are large, finding $\mathbf{L}$ such that $\mathbf{LL}^T = \mathbf{C}$ poses computational challenges. A method of finding $\mathbf{L}$ is the Cholesky decomposition by partitioning described below. To implement the simulation $\mathbf{Z}^S = \mathbf{Z}_s^* + \mathbf{LW}$ as described in earlier, let $\mathbf{G}$, the set of nodes at which it is desired to simulate the random function $\mathbf{Z}$, be partitioned into $\mathbf{G}_1, \mathbf{G}_2, \dots, \mathbf{G}_p$ where $\mathbf{G}_i$, $i = 1, 2, \dots, p$ contain r_i elements, $i = 1, 2, \dots, p$ and let $\mathbf{Z}^{G_i}$, $i = 1, 2, \dots, p$ be the corresponding partition of $\mathbf{Z}^G$. The covariance matrix of $\mathbf{Z}^G | \mathbf{Z}^D$, viz. $\mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12}$, then can be partitioned as

$$\begin{bmatrix} \mathbf{V}_{11} & \mathbf{V}_{12} & \cdots & \mathbf{V}_{1p} \\ \mathbf{V}_{21} & \mathbf{V}_{22} & \cdots & \mathbf{V}_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{V}_{p1} & \mathbf{V}_{p2} & \cdots & \mathbf{V}_{pp} \end{bmatrix}$$

where $\mathbf{V}_{ij}$ is an $r_i \times r_j$ matrix where $i, j = 1, 2, \dots, p$ and $r_1 + r_2 + \dots + r_p = M$. Let

$$\mathbf{L} = \begin{bmatrix} \mathbf{L}_{11} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{L}_{21} & \mathbf{L}_{22} & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{L}_{p1} & \mathbf{L}_{p2} & \cdots & \mathbf{L}_{pp} \end{bmatrix}$$

be the corresponding partition of the Cholesky factor of $\mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12}$. By equating

$$\mathbf{LL}^T = \mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12} = \begin{bmatrix} \mathbf{V}_{11} & \mathbf{V}_{12} & \cdots & \mathbf{V}_{1p} \\ \mathbf{V}_{21} & \mathbf{V}_{22} & \cdots & \mathbf{V}_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{V}_{p1} & \mathbf{V}_{p2} & \cdots & \mathbf{V}_{pp} \end{bmatrix} = \mathbf{V},$$

clearly, $\mathbf{L}_{11}\mathbf{L}_{11}^T = \mathbf{V}_{11}$ and, $\mathbf{L}_{i1}\mathbf{L}_{11}^T = \mathbf{V}_{i1}$, for $i = 1, 2, \dots, p$. For $p \geq i \geq j \geq 2$, it can be seen from the partitioning of $\mathbf{V}$ that,

$$\mathbf{V}_{ij} = \sum_{k=1}^j \mathbf{L}_{ik}\mathbf{L}_{jk}^T \quad \text{and hence,} \quad \mathbf{L}_{ij}\mathbf{L}_{jj}^T = \mathbf{V}_{ij} - \sum_{k=1}^{j-1} \mathbf{L}_{ik}\mathbf{L}_{jk}^T.$$

Denoting $\mathbf{S}_{ij} = \mathbf{V}_{ij} - \sum_{k=1}^{j-1} \mathbf{L}_{ik}\mathbf{L}_{jk}^T$ for $p \geq i \geq j \geq 2$, $\mathbf{L}_{jj}$ is the Cholesky factor of $\mathbf{S}_{jj}$ and $\mathbf{L}_{ij}$ satisfies $\mathbf{L}_{ij}\mathbf{L}_{jj}^T = \mathbf{S}_{ij}$. Using these equations, the Cholesky decomposition of large matrices can be found from the decomposition of much smaller matrices.

Finally,

$$\begin{aligned} \mathbf{Z}^S &= \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{Z}^D + \mathbf{LW} = \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{Z}^D + \begin{bmatrix} \mathbf{L}_{11} & \mathbf{0} & \mathbf{0} & \cdots & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{L}_{21} & \mathbf{L}_{22} & \mathbf{0} & \cdots & \cdots & \mathbf{0} & \mathbf{0} \\ \mathbf{L}_{31} & \mathbf{L}_{32} & \mathbf{L}_{33} & \cdots & \cdots & \mathbf{0} & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \ddots & \mathbf{0} & \mathbf{0} \\ \mathbf{L}_{p1} & \mathbf{L}_{p2} & \mathbf{L}_{p3} & \cdots & \cdots & \mathbf{L}_{p,p-1} & \mathbf{L}_{pp} \end{bmatrix} \begin{bmatrix} \mathbf{w}_1 \\ \mathbf{w}_2 \\ \mathbf{w}_3 \\ \vdots \\ \mathbf{w}_p \end{bmatrix} \\ &= \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{Z}^D + \begin{bmatrix} \mathbf{L}_{11}\mathbf{w}_1 \\ \mathbf{L}_{21}\mathbf{w}_1 + \mathbf{L}_{22}\mathbf{w}_2 \\ \mathbf{L}_{31}\mathbf{w}_1 + \mathbf{L}_{32}\mathbf{w}_2 + \mathbf{L}_{33}\mathbf{w}_3 \\ \vdots \\ \mathbf{L}_{p1}\mathbf{w}_1 + \mathbf{L}_{p2}\mathbf{w}_2 + \cdots + \mathbf{L}_{pp}\mathbf{w}_p \end{bmatrix} = \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{Z}^D + \sum_{i=1}^p \mathbf{L}^{(i)}\mathbf{w}_i \end{aligned}$$

where $\mathbf{L}^{(i)}$ is the i^{th} column of $\mathbf{L}$. If the matrix $\mathbf{C}_{21}$ =

$(\mathbf{C}_{21}^{(1)}, \mathbf{C}_{21}^{(2)}, \dots, \mathbf{C}_{21}^{(p)})^T$ is partitioned into p blocks,

compatible with the partition of $\mathbf{L}$, one may rewrite the above equations as

$$\mathbf{Z}^S = \begin{bmatrix} \mathbf{C}_{21}^{(1)} \mathbf{C}_{11}^{-1} \mathbf{Z}^D \\ \mathbf{C}_{21}^{(2)} \mathbf{C}_{11}^{-1} \mathbf{Z}^D \\ \mathbf{C}_{21}^{(3)} \mathbf{C}_{11}^{-1} \mathbf{Z}^D \\ \vdots \\ \mathbf{C}_{21}^{(p)} \mathbf{C}_{11}^{-1} \mathbf{Z}^D \end{bmatrix} + \begin{bmatrix} \mathbf{L}_{11} \mathbf{w}_1 \\ \mathbf{L}_{21} \mathbf{w}_1 + \mathbf{L}_{22} \mathbf{w}_2 \\ \mathbf{L}_{31} \mathbf{w}_1 + \mathbf{L}_{32} \mathbf{w}_2 + \mathbf{L}_{33} \mathbf{w}_3 \\ \vdots \\ \mathbf{L}_{p1} \mathbf{w}_1 + \mathbf{L}_{p2} \mathbf{w}_2 + \cdots + \mathbf{L}_{pp} \mathbf{w}_p \end{bmatrix}$$

$$= \begin{bmatrix} \mathbf{Z}_{(1)}^S \\ \mathbf{Z}_{(2)}^S \\ \mathbf{Z}_{(3)}^S \\ \vdots \\ \mathbf{Z}_{(p)}^S \end{bmatrix}, \text{ say.}$$

This equation shows that if the calculation of all $\mathbf{L}_{aj}, j \leq \alpha$, $\alpha \leq i$ has been completed, then, $\mathbf{Z}^{(1)S}, \mathbf{Z}^{(2)S}, \mathbf{Z}^{(3)S}, \dots, \mathbf{Z}^{(i)S}$, the simulations up to the i^{th} block can be obtained. If the calculations proceed row-wise and if $\mathbf{Z}$ and $\mathbf{W}_i$'s are appropriately multi-Gaussian, then the simulation is the Sequential Gaussian Simulation.

Conditional Simulation Using Successive Residuals

Let $\mathbf{D}$ be the set of locations where data is available and let $\mathbf{D}$ be partitioned into $\mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_l$. The grouping of data-locations into the partitions may be in any order. Thus $\mathbf{Z} = (\mathbf{Z}^D, \mathbf{Z}^G)^T$ is now partitioned into $(\mathbf{Z}^{D_1}, \mathbf{Z}^{D_2}, \dots, \mathbf{Z}^{D_l}, \mathbf{Z}^{G_1}, \mathbf{Z}^{G_2}, \dots, \mathbf{Z}^{G_p})^T$. The covariance matrix $\mathbf{C}$ of $\mathbf{Z}$ is correspondingly partitioned into $\mathbf{C} = [\mathbf{V}_{ij}]$ where $\mathbf{V}_{ij}$ is the ij^{th} block of the partition. The algorithm for computation of the lower-triangular matrix $\mathbf{L} = [\mathbf{L}_{ij}]$ where $\mathbf{L}\mathbf{L}^T = \mathbf{C}$, with $\mathbf{L}_{ij}$ corresponding to the ij^{th} block can be obtained by the algorithm described in the previous section with newly defined $[\mathbf{V}_{ij}]$. If $\mathbf{L}$ is rewritten as $\mathbf{L} = \begin{bmatrix} \mathbf{L}^{11} & \mathbf{0} \\ \mathbf{L}^{21} & \mathbf{L}^{22} \end{bmatrix}$ corresponding to $\begin{bmatrix} \mathbf{C}_{11} & \mathbf{C}_{12} \\ \mathbf{C}_{21} & \mathbf{C}_{22} \end{bmatrix}$, the required Cholesky decomposition of $\mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12}$ is given by $\mathbf{L}^{22}$. This avoids the explicit prior computation of the Schur complement $\mathbf{C}_{22} - \mathbf{C}_{21}\mathbf{C}_{11}^{-1}\mathbf{C}_{12}$ of $\mathbf{C}_{11}$ as required in the previous algorithm. The algorithm for Cholesky decomposition can be performed in multiple ways where $\mathbf{L}_{ij} = \left[\mathbf{V}_{ij} - \sum_{k=1}^{j-1} \mathbf{L}_{ik} \mathbf{L}_{jk}^T \right] \mathbf{L}_{jj}^{T-1}$ for $j \leq i$. This computation can be seen as a series of updating operations on $\mathbf{V}_{ij}$ that can be written as $\mathbf{V}_{ij}^{(k)} = \mathbf{V}_{ij}^{(k-1)} - \mathbf{L}_{ik} \mathbf{L}_{jk}^T$ where, the superscript in brackets denotes the stage of updating of $\mathbf{V}_{ij}$, with $\mathbf{V}_{ij}^{(0)} = \mathbf{V}_{ij}$.

One may write, $\mathbf{S}_{ij} = \mathbf{V}_{ij} - \sum_{k=1}^{j-1} \mathbf{L}_{ik} \mathbf{L}_{jk}^T = \xi_{ij}^{j-1}$ where, in the notation of Vargas-Guzmán and Dimitrakopoulos (2002), ξ_{ij}^{j-1} is the $j-1^{th}$ successive residual conditional covariance matrix corresponding to the i^{th} and j^{th} blocks.

Truncated Gaussian Simulation and Plurigaussian Simulation
The random function $\mathbf{Z} = \{\mathbf{Z}(x), x \in D\}$ may be such that some of the components of $\mathbf{Z}$ may be categorical. For example in an iron-ore deposit, at each location x , there may be different types of ore such as "hard-ore," "laminated ore," "soft-ore," and "blue-dust," based on physical parameters of the ore. Another variable of interest could be the value of $\text{Fe}_2\text{O}_3\%$ of the sample. A third variable could be a classification of the sample into an ordered list A,B,C,D based on the quality of ore vis-à-vis its industrial utility with A grade better than B and so on. Here, the random vector $\mathbf{Z}(x) = (Z_1(x), Z_2(x), Z_3(x))^T$ where $Z_1(x)$ is a nominal random variable and corresponds to the type of ore, $Z_2(x)$ is a numerical random variable and corresponds to $\text{Fe}_2\text{O}_3\%$ and $Z_3(x)$ is an ordinal random variable that corresponds to the quality of ore. It may be required to obtain simulations of all three types of random variables. In the sequel, the case where all components of $\mathbf{Z}$ are categorical is considered first.

For the purpose of discussion, consider $\mathbf{Z}$ to be a one-dimensional categorical random process. Let $F = \{F(x), x \in D\}$ be a random process taking values $1, 2, \dots, n$. Let $\mathbf{Y} = \{\mathbf{Y}(x), x \in D\}$ be a k -dimensional standard Gaussian random process where the components $Y_i, i = 1, 2, \dots, k$ are an independent standard Gaussian process coregionalized with F . Let $(A_1, A_2, \dots, A_n)$ partition $\mathcal{R}^k$ and define $F(x) = i \Leftrightarrow \mathbf{Y}(x) \in A_i, i = 1, 2, \dots, n$. Since F is defined through the process $\mathbf{Y}$, the process $\mathbf{Y}$ is considered to be latent with respect to F . Let $C_{ij}(\vec{h}) = E[I_{F(x)=i}(x)I_{F(x+h)=j}(x+\vec{h})] = P[F(x)=i, F(x+\vec{h})=j]$. It can be seen that $C_{ij}(h) = E[I_{A_i}(\mathbf{Y}(x))I_{A_j}(\mathbf{Y}(x+\vec{h}))] = \int \int g_{\mathbf{p}}(\vec{h})(\mathbf{u}, \mathbf{v}) d\mathbf{u} d\mathbf{v}$ where $g_{\mathbf{p}}(\vec{h})$ is the probability density function of $N_{2k}(\mathbf{0}, \mathbf{0}, \mathbf{1}, \mathbf{1}, \mathbf{p}(\vec{h}))$ where $\mathbf{p}(\vec{h}) = [\rho_{ij}(\vec{h})]$ with $\rho_{ij}(\vec{h}) = \text{Cov}(Y_i(x), Y_j(x+\vec{h})) = \begin{cases} \rho_i(\vec{h}) & \text{if } i=j \\ 0, & \text{otherwise} \end{cases}$, and the A_i are chosen such that $E[I_{A_i}(\mathbf{Y}(x))] = P[F(x)=i] = p_i(x)$, the proportion of the i^{th} category at x . The indicator functions $I_{A_i}(Y_i(x)) = \begin{cases} 1 & \text{if } Y_i(x) \in A_i \\ 0 & \text{otherwise} \end{cases} = \phi_i(Y_i(x), i = 1, 2, \dots, k$ are developed in terms of Hermite polynomials to give for the i^{th} categorical variable: $C_{Y_i}(\vec{h}) = E[I_{A_i}(Y_i(x))I_{A_i}(Y_i(x+\vec{h}))] = \left(1 - G(y_i(x))\right) \left(1 - G(y_i(x+\vec{h}))\right) + \sum_{n=0}^{\infty} \frac{H_{n-1}(y_i(x))H_{n-1}(y_i(x+\vec{h}))}{n!} \rho_i^n(\vec{h}) g(y_i(x))g(y_i(x+\vec{h}))$ where $C_{Y_i}(\vec{h})$ is the uncentered covariance of the indicator for the i^{th} category. $\hat{C}_{Y_i}(\vec{h})$ is estimated from data, from which an estimate $\hat{\rho}_i(\vec{h})$ of the function $\rho_i(\vec{h})$ is computed.

The process $\mathbf{Y}(x)$ that is simulated and the relation $F(x) = i \Leftrightarrow \mathbf{Y}(x) \in A_i$, $i = 1, 2, \dots, n$ are used to simulate F . This method of simulation of F is called *Truncated Gaussian Simulation* if $k = 1$, otherwise the simulation is called *Plurigaussian Simulation*. In the simulation procedure $\left[\rho_i(\vec{h})\right]$ has to be chosen so that $C_{ij}^S(\vec{h})$, the covariance of the simulated data, is the same as that of the model $C_{ij}(\vec{h})$ and $E[I_{A_i}(\mathbf{Y}^S(x))] = p_i(x)$ where $\mathbf{Y}^S(x)$ denotes the simulated random vector at x . If F represents a stationary process, $p_i(x) = p_i \quad \forall x$.

A limitation of the Truncated Gaussian Simulation technique is that when $\rho(\vec{h})$ is continuous, $P[Y(x) \in A_i, Y(x + \vec{h}) \in A_j] > P[Y(x) \in A_i, Y(x + \vec{h}) \in A_l] \quad \forall l : |l - i| > |j - i|$ for $\vec{h} : \rho(\vec{h}) > 0$, that is, if $F(x) = i$ then $F(x + \vec{h})$ is more likely to be the category j than the category l . This results in the simulation having an ordering and has to be borne in mind while choosing the assignment of categories to partitions of $\mathfrak{R}$. If such orderings are not observed in the data, and hence not desirable, this property is a limitation of the Truncated Gaussian Simulation technique (Galli et al. 1994). An early example of the use of Truncated Gaussian Simulation for generating the geometry of fluvio-glacial reservoirs can be seen in Matheron et al. (1987).

On the other hand, when $k > 1$, the A_i 's are partitions of $\mathfrak{R}^k$ and therefore afford more flexibility in assigning categories to partitions so that more complicated relations among categories can be incorporated in the assignment of the partitions. The relations between categories would hence be reflected in plurigaussian simulations (Armstrong et al. 2011). In practice the partitions A_i are chosen as k -dimensional rectangles in $\mathfrak{R}^k$.

In applications, $F(x)$ may be observed at a finite set of points $x_1, x_2, \dots, x_N$ and the task is to simulate $F(x)$ at locations $s_1, s_2, \dots, s_M$. The values of the latent random variables at locations $x_1, x_2, \dots, x_N$ are unknown except for constraints that if $F(x) = i$, then $\mathbf{Y}(x) \in A_i$. The simulation of $F(x)$ at $s_1, s_2, \dots, s_M$ is obtained by simulating $\mathbf{Y}$ at these locations subject to constraints on $\mathbf{Y}$ at $x_1, x_2, \dots, x_N$.

In practice, the first step consists of simulating $\mathbf{Y}(x_1), \mathbf{Y}(x_2), \dots, \mathbf{Y}(x_N)$ subject to $\mathbf{Y}(x_l) \in A_i$ if $F(x_l) = i$, $l = 1, 2, \dots, N$. To do this, it can be seen that the joint distribution of $\mathbf{Y}(x_1), \mathbf{Y}(x_2), \dots, \mathbf{Y}(x_N)$ is given by $h_N(\mathbf{Y}) = \frac{1}{k} g(\mathbf{Y}) \cdot \prod_{l=1}^N \left(I_{A_{F(x_l)}}(\mathbf{Y}(x_l)) \right)$, where $k = \int_{A_{F(x_1)}} \int_{A_{F(x_2)}} \dots \int_{A_{F(x_N)}} g(\mathbf{Y}) d\mathbf{Y}$, that is, the normalizing factor, and $\mathbf{Y} = (\mathbf{Y}(x_1)^T, \mathbf{Y}(x_2)^T, \dots, \mathbf{Y}(x_N)^T)^T$. The conditional probability functions of $\mathbf{Y}(x_i) \mid (\mathbf{Y}(x_j), j \neq i)$, called *full-conditional* (that is used in the Gibbs

sampler) are written as $h(\mathbf{Y}(x_i) \mid (\mathbf{Y}(x_j), j \neq i))$, $i = 1, 2, \dots, N$ and are given by $\frac{h_N(\mathbf{Y})}{h_{N-1}(\mathbf{Y}_i)}$, where $\mathbf{Y}_i$ is $\mathbf{Y}$ without the vector $\mathbf{Y}(x_i)^T$, that is, without the i^{th} vector. When $\mathbf{Y}$ is multi-Gaussian, $\mathbf{Y}_i$ is multi-Gaussian, but the probability functions $h_N(\mathbf{Y})$, $h_{N-1}(\mathbf{Y}_i)$ and $\frac{h_N(\mathbf{Y})}{h_{N-1}(\mathbf{Y}_i)}$ are not multi-Gaussian.

The first step of plurigaussian simulation consists of generating observations from $h_N(\mathbf{Y})$. When this is done, the latent variable will be available at all $x_1, x_2, \dots, x_N$ respecting the constraints $\mathbf{Y}(x_l) \in A_i$ if $F(x_l) = i$, $l = 1, 2, \dots, N$. The second step consists of generating $F(x)$ at locations $s_1, s_2, \dots, s_M$. This reduces to one of generating the Gaussian vectors $\mathbf{Y}(s_1), \mathbf{Y}(s_2), \dots, \mathbf{Y}(s_M)$ conditional to the vectors $\mathbf{Y}(x_1), \mathbf{Y}(x_2), \dots, \mathbf{Y}(x_N)$ that are now available and obtaining the corresponding category using $F^{-1}(\mathbf{Y}(s))$. The method of performing the first step of the simulation is a modification of the Gibbs Sampler and was first suggested in the geostatistical context by Freulon and de Fouquet (1993). For the second step any of the methods that perform conditional simulation can be used, such as the sequential Gaussian simulation method, the L-U decomposition method, Accept-Reject method or the Gibbs Sampler. Since the Gibbs sampler is used in the first step, it is often convenient to use the Gibbs Sampler for the second step also. The details of the Gibbs Sampler are given in the section below.

The Gibbs Sampler

The *Gibbs Sampler* is a particular instance of the *Metropolis-Hastings Algorithm* (M-H algorithm) used to generate a Markov chain with a given stationary distribution f . If it is desired to generate an observation from $f_{\mathbf{Y}}$, then the M-H algorithm constructs an ergodic Markov chain whose state-space is the range $\mathbf{S}$ of $\mathbf{Y} = (\mathbf{Y}_1^T, \mathbf{Y}_2^T, \dots, \mathbf{Y}_N^T)^T$ and whose stationary distribution, called the *target distribution*, is $f_{\mathbf{Y}}$. Let $q(\mathbf{y} \mid \mathbf{v})$ be a conditional density called the *instrumental distribution*, where $\mathbf{y} = (\mathbf{y}_1^T, \mathbf{y}_2^T, \dots, \mathbf{y}_N^T)^T$ and $\mathbf{v} = (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_N^T)^T \in \mathbf{S}$. Suppose the Markov chain $\mathbf{X}^{(t)}$ is in state $\mathbf{v}$ at time t , that is, $\mathbf{X}^{(t)} = \mathbf{v}$. An observation $\mathbf{y}$ is generated from $q(\cdot \mid \mathbf{v})$.

At time $t + 1$, $\mathbf{X}^{(t+1)} = \begin{cases} \mathbf{y} & \text{with probability } \rho(\mathbf{v}, \mathbf{y}) \\ \mathbf{v} & \text{with probability } 1 - \rho(\mathbf{v}, \mathbf{y}) \end{cases}$ with $\rho(\mathbf{v}, \mathbf{y}) = \min \left[\left(\frac{f_{\mathbf{Y}}(\mathbf{y}) \cdot q(\mathbf{v} \mid \mathbf{y})}{f_{\mathbf{Y}}(\mathbf{v}) \cdot q(\mathbf{y} \mid \mathbf{v})} \right), 1 \right]$. The kernel of the Markov chain $\mathbf{X}^{(t)}$ so generated verifies the detailed balance condition with $f_{\mathbf{Y}}$ as its stationary distribution (Robert and Casella 2004). Thus, for large t , $\mathbf{X}^{(t)}$ converges in distribution to $f_{\mathbf{Y}}$. The important feature of the M-H algorithm is that an observation from $f_{\mathbf{Y}}$ is generated by generating observations from $q(\cdot \mid \mathbf{v})$.

The Gibbs sampler is a special case of the M-H algorithm where the transition from $\mathbf{X}^{(t)} = \mathbf{v}$ to $\mathbf{X}^{(t+1)} = \mathbf{y}$ where

change from $\mathbf{v} = (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_N^T)^T$ to $\mathbf{y} = (\mathbf{y}_1^T, \mathbf{y}_2^T, \dots, \mathbf{y}_N^T)^T$ occurs by change of a single vector $\mathbf{v}_i$, say, from $\mathbf{v}_i$ to $\mathbf{y}_i$, all other components remaining the same, with $\mathbf{y}_i$ drawn from $q_i(\mathbf{y}_i | (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_{i-1}^T, \mathbf{v}_{i+1}^T, \dots, \mathbf{v}_N^T)^T)$ which is the conditional distribution of $\mathbf{Y}_i | \mathbf{Y}_j, j \neq i$, that is, the full-conditional. This gives $\rho(\mathbf{v}, \mathbf{y}) = 1$, implying a change from $\mathbf{X}^{(t)} = \mathbf{v}$ to $\mathbf{X}^{(t+1)} = \mathbf{y}$ within every step of the algorithm.

Thus, the algorithm is as follows: (i) Suppose $\mathbf{X}^{(t)} = \mathbf{v} = (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_N^T)^T$ at time t . An integer is drawn at random between 1 and N . Let that integer be i . (ii) Generate $\mathbf{y}_i$ from the full-conditional $q_i(\cdot | (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_{i-1}^T, \mathbf{v}_{i+1}^T, \dots, \mathbf{v}_N^T)^T)$. Then $\mathbf{X}^{(t+1)} = \mathbf{y} = (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_{i-1}^T, \mathbf{y}_i^T, \mathbf{v}_{i+1}^T, \dots, \mathbf{v}_N^T)^T$. (iii) Assign $\mathbf{v} = (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_{i-1}^T, \mathbf{y}_i^T, \mathbf{v}_{i+1}^T, \dots, \mathbf{v}_N^T)^T$ and loop to the first step of the algorithm with $t = t + 1$. The procedure may be started by setting $\mathbf{X}^{(0)} = \mathbf{0}^T$.

In Plurigaussian (or Truncated Gaussian) simulation, the full-conditionals $q_i(\mathbf{y}_i^T | (\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_{i-1}^T, \mathbf{v}_{i+1}^T, \dots, \mathbf{v}_N^T)^T)$ are $h(\mathbf{Y}(x_i) | (\mathbf{Y}(x_j), j \neq i)), i = 1, 2, \dots, N$. In practice, each component $Y_l(x_i), l = 1, 2, \dots, k$ of $\mathbf{Y}(x_i)$ is updated by drawing an observation from the conditional distribution $h_l(Y_l(x_i) | (\mathbf{Y}(x_j), j \neq i)), i = 1, 2, \dots, N, l = 1, 2, \dots, k$ which is a Gaussian $N(y_{l,SK}^*(x_i), \sigma_{l,SK}^2(x_i))$, where $y_{l,SK}^*(x_i)$ and $\sigma_{l,SK}^2(x_i)$ are the simple kriging estimate and variance of estimation, respectively, of the l^{th} component of $\mathbf{Y}(x_i)$ obtained using $Y_l(x_j), j \neq i$. The estimation of parameters of the Gaussian conditional distribution reduces to simple (auto-) kriging if the components of the process $\mathbf{Y}$ are independent and hence spatially orthogonal. At the first stage of Plurigaussian or Truncated Gaussian Simulation, the simulation proceeds along the lines indicated previously. At time t let the random vector $\mathbf{Y}^{(t)} = (\mathbf{y}^{(t)}(x_1)^T, \mathbf{y}^{(t)}(x_2)^T, \dots, \mathbf{y}^{(t)}(x_N)^T)^T$. A number between 1 and N is chosen randomly and i is set equal to this number. Values $y_l^{**}(x_i) = y_{l,SK}^*(x_i) + \sigma_{l,SK}(x_i) \cdot u, l = 1, 2, \dots, k$, where u is drawn independently from $N(0, 1)$ are generated. The random vector $\mathbf{Y}^{(t+1)}$ is generated by setting $\mathbf{y}^{(t+1)}(x_i) = \begin{cases} \mathbf{y}^{**}(x_i) & \text{if } \mathbf{y}^{**}(x_i) \in A_{F(x_i)} \\ \mathbf{y}^{(t)} & \text{otherwise} \end{cases}$, where $\mathbf{y}^{**}(x_i) = (y_1^{**}(x_i), y_2^{**}(x_i), \dots, y_k^{**}(x_i))^T$ and retaining $\mathbf{y}^{(t+1)}(x_j) = \mathbf{y}^{(t)}(x_j), j \neq i$ otherwise. The simulation is started by arbitrarily setting $\mathbf{Y}^{(0)} = (\mathbf{y}^{(0)}(x_1)^T, \mathbf{y}^{(0)}(x_2)^T, \dots, \mathbf{y}^{(0)}(x_N)^T)^T$ where $\mathbf{y}^{(0)}(x_i) \in A_{F(x_i)}, i = 1, 2, \dots, N$, that is, respecting the constraints at each x_i . When t is large, a kN -dimensional vector $\mathbf{Y} = (\mathbf{y}(x_1)^T, \mathbf{y}(x_2)^T, \dots, \mathbf{y}(x_N)^T)^T$ is generated that respects constraints $A_{F(x_i)}, i = 1, 2, \dots, N$ and has the desired covariance. This is the first stage of Plurigaussian Simulation. The generated vector can be then used to condition the simulation $\mathbf{Y} = (\mathbf{Y}(s_1)^T, \mathbf{Y}(s_2)^T, \dots, \mathbf{Y}(s_M)^T)^T$ in the second stage of the

simulation procedure. The final step consists of obtaining the simulated categories at $s_1, s_2, \dots, s_M$ as $F(s_i) = F^{-1}(\mathbf{Y}(s_i))$.

If the Gibbs sampler is used for both the first and second stages of the Plurigaussian (or Truncated Gaussian) procedure, both stages can be incorporated into a single operation by considering simulation of the $(k \times (M + N))$ random vector with the first corresponding to data locations and the acceptance criteria applies only to the first kM components. If M or N are very large windowing will help in reducing computation at the cost of accuracy of reproduction of the covariance function. This can be remedied by methods such as simulated annealing or placing restrictions on the transition probabilities (Emery et al. 2014).

In the Plurigaussian (or Truncated Gaussian) technique, at time $t + 1$, the Gibbs sampler generates $Y_l^{t+1}(x_i)$, the l^{th} component of the randomly chosen vector $\mathbf{Y}^{(t+1)}(x_i)$ independent of components $j \neq l$. If components of the plurigaussian process are chosen to be independent, calculation of the simple (auto) kriging estimate and variance of estimation of $Y_l(u), u \in (x_1, x_2, \dots, x_N, s_1, s_2, \dots, s_M), l = 1, 2, \dots, k$ requires a one-time computation of each $\mathbf{C}_{Y_l}^{-1}, l = 1, 2, \dots, k$. An alternate method after Galli and Gao (2001) consists of using the Gibbs sampler to generate an M and N -dimensional vector $X_l, l = 1, 2, \dots, k$ with respective covariance matrices $\mathbf{C}_{Y_l}^{-1}, l = 1, 2, \dots, k$ and then taking $Y_l = \mathbf{C}_{Y_l} X_l$. This gives $\text{Cov}[Y_l] = \mathbf{C}_{Y_l} \mathbf{C}_{Y_l}^{-1} \mathbf{C}_{Y_l} = \mathbf{C}_{Y_l}$, the desired covariance. Generating the random vector X_l using the Gibbs Sampler requires only $[\mathbf{C}_{Y_l}^{-1}]^{-1} = \mathbf{C}_{Y_l}$ and hence avoids the one-time inversion of matrices $\mathbf{C}_{Y_l}, l = 1, 2, \dots, k$. Examples of the use of the Gibbs sampler in Truncated Gaussian and Plurigaussian simulation can be seen in Emery (2007a, b) or Arroyo et al. (2012),

If a categorical random variable $F(x)$ is observed along with a numerical random vector $\mathbf{Z}(x)$ at locations $x_1, x_2, \dots, x_N$, then $F(x)$ and $\mathbf{Z}(x)$ can be co-simulated at locations $s_1, s_2, \dots, s_M$ (see for example, Maleki and Emery 2015). After generating $\mathbf{Y}(x)$ at $x_1, x_2, \dots, x_N$ obeying constraints with respect to $F(x)$, as discussed previously, the cross covariance matrix functions $\mathbf{C}_{YZ}(\vec{h})$ of $\mathbf{Y}$ and $\mathbf{Z}$ can be modeled using data at $x_1, x_2, \dots, x_N$ and used for simulation (by cokriging) at $s_1, s_2, \dots, s_M$.

Multi-Point Simulation (SNESIM)

As mentioned previously, two-point statistics such as covariance or variogram only ensures reproduction of features of the random function Z that can be described by its second-order moments. Complex features described by physical geometries of specific nature require inference of higher dimensional joint distributions which can only be done by using multi-point statistics, that is, statistics defined in terms of more than two random variables (Journel and Alabert 1989). The distributions of these statistics need to be modeled. Iterative

methods such as neural-networks have been used to infer parameters of the distributions of such mp-statistics. A non-parametric multipoint method for estimating the distribution of mp-statistics was given by Guardiano and Srivastava (1993). Although innovative, this had the limitation of requiring repeated scanning of training images for determining relevant conditional distributions at each location and hence was very CPU-intensive. Strebelle (2002) introduced *SNESIM* (Single Normal Equation Simulation) which greatly reduced the CPU requirement by using search-trees for determining conditional probability distribution functions of the required multipoint statistics. More recent advances, in the use of multipoint statistics for joint simulation can be seen in Mariethoz and Caers (2015), Minniakhmetov and Dimitrakopoulos (2017), and Yao et al. (2020).

Let Z be a one-dimensional random process where the random variable $Z(x)$ at location x is either a categorical variable taking K different values, or a numerical random variable discretized into K levels, labeled as $1, 2, \dots, K$. Let s be a location where Z has not been observed. It is desired to obtain an observation from $Z(s) \mid \left(Z(s + \vec{h}_\alpha) = k_\alpha, \alpha = 1, 2, \dots, N \right)$ where $k_\alpha \in [1, K]$. The set $\{ \vec{h}_\alpha, \alpha = 1, 2, \dots, N \} = \tau_N$, say, is called the data-geometry. The data-geometry around the location s is chosen so that it guides reproduction of the physical geometry around the location s . Let $T = \prod_{\alpha=1}^N$

$(I_{Z(s+\vec{h}_\alpha)=k_\alpha}(s+\vec{h}_\alpha))$ and let $W_k = I_{Z(s)=k}(s)$, where $I_{Z(s+\vec{h}_\alpha)=k_\alpha}(s+\vec{h}_\alpha) = \begin{cases} 1 & \text{if } Z(s+\vec{h}_\alpha) = k_\alpha \\ 0 & \text{otherwise} \end{cases}$ and $I_{Z(s)=k}(s) = \begin{cases} 1 & \text{if } Z(s) = k \\ 0 & \text{otherwise} \end{cases}$. The random variable T takes the

value 1 whenever the random variables $Z(s + \vec{h}_\alpha) = k_\alpha, \alpha = 1, 2, \dots, N$ in the data geometry τ_N around s . The problem now is to estimate $P[W_k | T]$. At the heart of the SNESIM algorithm is the *single normal equation* given by $P[W_k = 1 | T] = E[W_k] + \frac{\text{Cov}(W_k, T)}{\text{Var}(T)}(T - E[T])$. When $T = 1$, this becomes $P[W_k = 1 | T = 1] = E[W_k] + \frac{\text{Cov}(W_k, T)}{\text{Var}(T)}(1 - E[T]) = E[W_k] + \frac{\text{Cov}(W_k, T)}{E[T]}$. The mp-statistics used in the SNESIM algorithm are $\text{Cov}(W_k, T)$ and $E[T]$. Let $I(u, j) = \begin{cases} 1 & \text{if } (Z(u) = j, Z(u + \vec{h}_\alpha) = k_\alpha, \alpha = 1, 2, \dots, N) \\ 0 & \text{otherwise} \end{cases}$ and let $\hat{f}_k = \frac{\#\{u: I(u, k) = 1\}}{\sum_{j=1}^K \#\{u: I(u, j) = 1\}}$ where u are locations in the training

data sets. The $\hat{f}_k, k = 1, 2, \dots, K$ are estimates of the conditional probability $f_k = P[W_k = 1 | T = 1]$. The simulated value $z^s(s)$ is obtained by drawing from $\hat{f}_k$. The SNESIM algorithm proceeds by tracing a random path over the set $\{s\}$ of all locations at which observations on Z are required to be generated. When a value is generated at any location s , that location is treated as a data location in defining the data-

geometry for any subsequent location to be simulated. If in addition to Z , soft data are available, this information can also be included by taking it as part of the conditioning data. In practice a data-geometry $\tau_{n'}$ with $n' \leq n$ may be chosen so that $\hat{f}_k, k = 1, 2, \dots, K$ can be estimated in a stable manner.

Other Simulation Methods

Historically, in geosciences, simulations of random fields Z were first performed using the “Turning Bands” algorithm initially proposed by Matheron (1973). This method generates non-conditional simulations in 2D and 3D by first simulating values along a finite set of N lines spread uniformly in 2D or 3D with appropriate one-dimensional covariances $C^{(1)}\left(\left|\vec{s}\right|\right)$ corresponding to a desired isotropic covariance $C\left(\left|\vec{h}\right|\right)$ using standard techniques such as moving averaging, where $|\vec{s}|$ is the projection of $\vec{h}$ onto the lines. Let $z_i(x)$ be the value on the i^{th} line at a point closest to the point x at which simulation is desired, that is, at the foot of the perpendicular from the point x onto the line, or within a “band” around the foot. The simulated value $z(x)$ is obtained as $z(x) = \frac{1}{\sqrt{N}} \sum_{i=1}^N z_i(x)$ (Journal and

Huijbregts 1978). For simulation in 3D due to symmetry, simulation along 15 lines is sufficient to generate non-conditional simulations at desired locations (such as at grid-nodes or data-locations) with the desired covariances. Conditional simulations (i.e., conditioned to observations on Z) are obtained by using the non-conditional simulation to compute “isomorphous” errors at grid nodes and adding them to the kriged values at grid nodes as explained previously in section “Simulation of a Second-Order Stationary Process”.

Probability Field Simulation is another technique first proposed by Froidevaux (1993) that is used to generate multiple maps conditional to given observations on a random field Z . Here, it is assumed that at all points s where a simulated value is to be generated, an estimate $\hat{F}_{Z(s)}(z|N)$ of the conditional distribution of $Z(s) \mid N$, where N denotes data $z(x_1), z(x_2), \dots, z(x_N)$, is known. First, realizations $u(x)$ of random variables $U(x) \sim U(0, 1)$ are generated at each x with a given covariance function $C_U(\vec{h})$. The simulated value at s is then $z^s(s) = \hat{F}^{-1}(u(x))$. The covariance $C_U(\vec{h})$ is modeled using an appropriate transform $U = \phi(Z)$ such that $U(x) \sim U(0, 1)$ to generate $u(x_1), u(x_2), \dots, u(x_N)$ at data locations. A commonly used transform is $u(x) = \frac{r(x)}{N}$, where $r(x)$ is the rank of $z(x)$ among the N data. Although lacking in strict theoretical justification, Probability Field Simulation is used in applications for rapid generation of multiple realizations of maps.

Substitution Random Fields are also used to generate models for random functions by the composition of a directing function and a coding function. The random function Z is written as $Z(x) = Y(T(x))$, where $T(x)$ is the directing function and Y is the coding process. This enables the

generation of wide variety of stochastic processes. The structure can be used for non-conditional and conditional simulations. Details of algorithms are given in Lantuéjoul (2002).

Other stochastic approaches to simulation that emphasize the incorporation of geometric features that need to be reproduced include the Boolean models that consist of the union of independent geometric bodies (compact sets in $\mathfrak{R}^d$) of varied sizes, shapes, orientations, and internal geometry as per a specified probability distribution around random (Poisson) seeds generated in space. Boolean models form the basis for generation of random sets and are an integral part of several other models used in geostatistical simulations that take a direct approach to reproducing geometric features characteristic of a natural process. Object-based models are a kind of random genetic models wherein geological information is incorporated in simulations through generalizations of the Boolean model. The basic steps in object-based simulation consist of the following: (i) Generating points x , called germs, in the domain $D \subset \mathfrak{R}^d$. This may be done using a Poisson point-process X with a chosen intensity. (ii) An object $A(x)$ is associated with each germ x from a finite collection of such objects which are compact sets in $\mathfrak{R}^d$. To each $A(x)$ a value $V(x)$ drawn from a random process is assigned (iii) At a point $y \in \mathfrak{R}^d$, the random function Z to be simulated is assigned the value $Z(y)$ by considering all objects that contain y . Ways in which the value of $Z(y)$ can be assigned include addition or maximum of all values assigned to objects containing y or the value assigned to the last object that covers y when the Boolean objects are generated multiple times (Serra 1987, 1988; Lantuéjoul 2002). For example, in the

“dilution model,” $Z(y) = \sum_x V(x) I_{A(x)}(y)$ where $I_{A(x)}(y) = \begin{cases} 1 & \text{if } y \in A(x) \\ 0 & \text{otherwise} \end{cases}$. In the Boolean random function model $Z(y) = \max_x V(x) I_{A(x)}(y)$. In the “dead-leaves model” of Matheron (1968) and Jeulin (1980, 1989) Boolean random sets are generated multiple times and indexed by t and objects $A(x, t)$ refer to any object placed at x at time t with a corresponding value $V(x, t)$. The value $Z(y) = V(x) I_{A(x, T)}(y)$ where T corresponds to the most recent object (leaf) that contains y .

Object-based methods have been widely used for simulating fluvial reservoirs. These methods incorporate details of fluvial architecture and the hierarchy of geological processes in the simulation procedure in the form of geological rules translated into stochastic terms (Pycrz and Deutsch 2014). The steps mentioned above are modified accordingly (Haldorsen and Lake 1984; Haldorsen and Damsleth 1990; Georgsen and Omre 1993). Although object-based methods generate very realistic 2 and 3 dimensional images, they have the drawback that conditioning to data is difficult (Matheron et al. 1987). Object-based simulation techniques are also often

combined with other simulation techniques wherein internal features of objects are in-filled using pixel-based techniques.

Simulated annealing is an optimization technique where a chosen objective function is minimized proceeding through an accept-reject procedure at each step where the probabilities of acceptance of the simulation step is gradually reduced till convergence of the objective function to the accepted minimum occurs. The objective function is chosen to reflect the purpose of simulation (Pycrz and Deutsch 2014).

Concluding Remarks

The principal aim of this chapter has been to explain the theoretical foundations of the most important techniques and developments in, what may be called, “classical (two-point) geostatistics.” Methods based on higher order moments, that is, multipoint statistics are briefly reviewed. The importance of these developments lies in the fact that many of the advances in theory and aspects of their practical implementation were made in response to requirements that arose in industrial applications. The assumptions needed to make use of theoretical results may often seem restrictive when dealing with outcomes of some of the complex processes that require to be modeled. With advances in computing power, the need for making simplifying assumptions has diminished and more direct methods of learning from data have been gaining importance. Exploratory data analysis in higher dimensions and extracting information from “big-data,” the use of artificial intelligence (AI) and machine-learning (ML) are increasingly applied to capture the essence of patterns in complex processes for the purpose of modeling, prediction and decision-making in geoscience applications. Nevertheless, classical techniques provide elegant tools that can be applied very effectively whenever data-analysis shows that assumptions required for modeling are satisfied.

GeoSyntax

Cedric M. Griffiths

StrataMod Pty. Ltd., and Curtin University, Perth, WA, Australia

Definition Consideration of Gressly’s original facies concept, and the formal application of “Walthers Law” suggested the basis of a succession analysis tool that could be used to: (a) match or correlate adjacent sections or wells via “Syntactic Pattern Recognition,” (b) act as the basis of quantitative hypothesis testing in stratigraphic evolution, (c) enable forward simulation of stratigraphic successions that test current understanding of facies association.

“GeoSyntax” is based on the development of a grammar of unit associations, and the parsing of lithological units defined either by hand specimen description, wire-line log characteristics, or theoretical facies associations.

Background

The philosophical basis for the geoSyntax approach to machine-assisted interpretation was first published by Griffiths (1989, 1990). Further work by Duan (1996 to 2001) expanded this to two-dimensional sections, and Hill (2007 to 2009) expanded the concept further to conditioned two-dimensional channel map forms and three-dimensional volumes using 3D-plex grammars.

Because of the human psychological necessity to reduce information to “chunks” for efficient processing (Griffiths 1989, 1990) as described by Miller (1956), classification forms an essential role in the observational sciences, and yet the theoretical process of classification itself has not been subjected to much debate in the geological literature, despite playing a central role in geological interpretation. The language of geological rules, the lingua franca of geological discourse, is composed largely of classes derived from subdivisions of observations. As an example, take this description of a canyon-fill deposit: “localised sand-prone intervals, possibly sand filled leveed feeder channels . . . local areas of high amplitude, internally mounded, discontinuous reflections.”

This description contains at least eight classifications (“local,” “sand,” “possible,” “levee,” “feeder,” “channel,” “high,” “mounded,” “discontinuous”), and a mixture of genetic, descriptive, fuzzy, and “hard” classes. A machine-based interpreter would have severe problems with many of these classifications, as would a geologist attempting to put numbers on these characteristics for quantitative testing of hypotheses.

Essential Concepts of the GeoSyntax Approach

A formal syntactic system has been developed for combining such qualitative/semiquantitative classes without the need for rigorous numerical treatment. The need to provide fast and efficient compilers for computer languages led to various ways of representing this structure, or “syntax.” One widely used syntactic system uses the “Backus- Naur-Form” (BNF) notation which was first developed to define the syntax of Algol 60 (Chomsky 1957). In the fields of stratigraphy and basin analysis there are a few stated principles such as:

- (i) Walther's Law of Succession of Facies (Walther 1893): which states that in a succession with no breaks (i.e., faults or erosional unconformities) only those facies that are to be found beside each other at the present time can be superimposed in vertical section.
- (ii) Law of Superposition of Strata: which states that in any succession of strata the beds were deposited in a simple vertical order from base to top.
- (iii) Gressly's Facies concept (Gressly 1838): which states that lateral changes in physical characteristics of rocks at a mappable scale are identified as discrete units.

The facies concept has been subjected to various interpretations, but Gressley's original sense, of being a collection of physical properties that are distinguishable from those of neighboring rocks at a chosen scale, is suitable for GeoSyntax purposes (Moore 1949). Walther's Law has potential as a predictive tool if used carefully, and may be used to form the basis of a syntactic rule set that translates vertical well or outcrop observations to three-dimensional facies volumes. For any given depositional system at a given scale, there will be a set of facies relationships such that a traverse in a given direction in relation to the direction of flow of the transport medium would be expected to encounter a succession of descriptive facies units with an estimated probability. In stratigraphy we thus have a set of terminal symbols (facies) that, if they are capable of being unambiguously mapped within a present-day depositional system, should also be capable of being identified, using the same syntax, from borehole successions if there were no intervening periods of erosion.

```

<Upper.channel> ::= <Bar.top> | <VA>
<VA> ::= f | <VA> g
<Bar.top> ::= f | e | d
<Lower.channel> ::= <Channel.floor> |
<Lower.channel> c | <Lower.channel> b
<Channel.floor> ::= ss | a |
<Channel.floor> a
<Channel.fill> ::= <Lower.channel>
<Upper.channel> | <Channel.fill> <Upper.
channel>

```

```

<Channel.succession> ::= <Channel.fill>
<Channel.fill> | <Channel.succession>
<Channel.fill>
<Channel.succession> ::= <Channel.
succession> <Upper.channel>

```

where: ss = scoured surface, a = poorly defined trough cross-bedding, b = well-defined trough cross-bedding, c = large planar tabular cross beds, d = small planar tabular cross beds, e = isolated scour fills, f = ripple cross laminated silts and muds, g = low angle inclined stratification, VA = vertical accretion unit.

The simple one-dimensional Battery Point channel fill model (Fig. 1), which is itself derived from a Markov analysis of several field sections, can provide an example of a simple syntax derived from theoretical considerations. [GeoSyntax, Fig. 1.tif].

Examination of the “summary” succession might lead to the design of the following context-free BNF syntax (from the base upwards).

Each BNF production rule contains:

a symbol “::=”, which means “is comprised of”.

a nonterminal symbol (symbol to the left of::=).

one or more terminal symbols (symbols to the right of::=).

Terminal symbols are the elementary symbols of the language defined by a formal grammar. Nonterminal symbols are replaced by groups of terminal symbols according to the production rules. The terminals and nonterminals of a particular grammar are two disjoint sets. Where there is more than one terminal symbol these are separated by the “or” symbol (|), or a space which is interpreted as “followed by.” This implies that the succession is directional and read from base to top in an outcrop or borehole, or (after Walther's Law) from proximal to distal.

The simple grammar and syntax described above has captured the essence of a “Channel Fill” succession as understood by Cant and Walker. This understanding can be used in several ways: (a) to simply and formally define the essence of “Channel Fill” and its possible variability in a way that can be understood by both human and machine interpreters; (b) to enable multiple synthetic “Channel Fill” units to be used to forward model channel successions; (c) to enable an unknown section to be tested automatically for degree of “Channel Fill”-ness. Ranges of physical properties and probabilities (such as thickness, lateral extent, porosity, and permeability) may be attributed to each of the terminal symbols as described in Duan et al. (1999) for generating probabilistic 2D stratigraphic sections. To produce a synthetic succession the highest level nonterminal symbol, in this case “Channel.Succession,” must be completely replaced by terminal symbols using the grammatical rules. Terminal symbols represent basic geological observations: scoured surface, poorly defined trough cross-bedding, well-defined trough cross-

GeoSyntax, Fig. 1 Battery point summary channel fill succession. (Derived from Walker and Cant 1984, Fig. 20, p. 83)

bedding, large planar tabular cross beds, small planar tabular cross beds, isolated scour fills, ripple cross-laminated silts and muds, and low angle inclined stratification. By convention, names of terminal and nonterminal symbols start with lower-case and upper-case letters, respectively.

Formally speaking, this is an inverted BNF grammar. It is presented this way for two reasons. The first is that computationally it is more efficient, and secondly it is easier to follow the progressive interpretation of nonterminal to terminal symbols while reading. It is worth noting that grain size is included explicitly in only one terminal symbol (f). The remainder are a mixture of genetic and descriptive structural/textural facies. When reconstructing a sedimentary body from limited observational data, geologists will typically produce the simplest model that honors the available data.

The geosyntactic method is not only object-based but it is also object-oriented. Object-oriented means that a geological object can be represented by a single symbol of variable size rather than a collection of rectangular cells, and hence the simulation does not have a fixed resolution dependent on cell size. The syntactic method provides a holistic framework to describe a complete depositional environment in a single grammar and has the potential to describe sophisticated patterns in a simple format. Once the user has selected or designed a suitable grammar the generation of geological models is performed automatically by a computer program

called the parser. Parsing is the process of applying the legal components of a grammar according to the rules described in the syntax to either interpret or generate “legal” successions of terminal symbols. In a stratigraphic context the grammar is the set of rules specifying the sedimentary units that are associated with a specific environment and their relationships as defined by the syntax. The basic principles of geosyntax as outlined above may be expanded in application and complexity to address the simulation of two- and three-dimensional sediment bodies.

Current Status

GeoSyntax allows for the concise definition of complex facies relationships, and enables their quantitative regional comparison by combining an attributed grammar with a “Generalised Levenshtein Distance.” In this case, each of the facies symbols contains one or more attributes, (a “string with attributes” in symbolic computation language). For instance, the bottom to top facies type of a typical channel sedimentary facies succession can be coded by symbols as shown in the Channel Fill case above, and each facies (terminal symbol) can be associated with a number or an attribute representing the thickness of each facies as described in detail by Duan et al. (2001a, b; Duan 2017) combining an attributed grammar, with a “Generalised Levenshtein Distance.”

Extension to Two- and Three-Dimensional Sedimentary Bodies

The above examples used “facies” as terminal symbols (e.g., “small planar tabular cross beds”), and environments (e.g., “Upper.channel”) as nonterminal symbols. However, it proved also possible to use geometric shapes as symbols in a

grammar describing channel behavior in two-dimensional vertical section as shown in Figs. 2 and 3, and two-dimensional plan view as shown in Fig. 4.

A set of probabilistic rules for a meandering channel system. Nonterminal symbols are written in capitals, MDCH is the start symbol (Table 1).

GeoSyntax, Fig. 2 Basic shape of terminal symbols: *fp* floodplain, *ov* overbank, *cs* crevasse splay and *ch* channel fill deposits. (Derived from Hill and Griffiths 2006))

GeoSyntax, Fig. 3 Two-dimensional simulated vertical section based on the syntax shown in Fig. 2, conditioned on 2 hypothetical wells (black lines): 10 time slices using a grammar which generates nested channels.

Dark gray = floodplain muds, light gray = channel fill, black = crevasse splay deposit, white = overbank deposits. (Derived from Hill and Griffiths 2006))

GeoSyntax, Fig. 4 Two-dimensional plan-view conditioned geosyntax simulation. (Derived from Hill and Griffiths 2009)
A – A finite-state diagram illustrating the rules which generate parent symbols. The states are outlined in boxes and have 3 letter labels, the start state for the grammar is FAN. The rules are represented by arrows which go from initial state to final state. Each rule has (a) a number, (b) the probability of the rule in brackets, and (c) a simple representation

of the parent symbol generated by that rule.
B – Examples of maps of channel-related deposits generated by the parser: (a) an unconditioned map; (b) and (c) maps generated using the same two conditioning symbols. Light gray 1/4 overbank deposits; dark gray 1/4 splay deposits; white 1/4 channel fill; black 1/4 channel conditioning symbol.

GeoSyntax, Table 1 A set of rules for a meandering channel system (MDCH). Terminal symbols (facies) start with small letters and non-terminal symbols (interpretation) are in capital letters. MDCH is the start symbol for a forward simulation, or the final interpretation for an inverse model

No.	Head		Tail(s)	Probability of the first tail
1	MDCH	→	fp fp + MD	1.0
2	MD	→	MDL MDR	0.5
3	MDR	→	fp + fpOv + ov + ovCH + chR + CHFP	1.0
4	MDL	→	FPCH + chL + chOv + ovR + fp + MDCH	1.0
5	CHFP	→	CSFP OVFP	0.7
6	FPCH	→	FPCS FPOV	0.7
7	CSFP	→	chCs + cs + CSFP + fp + MDCH	1.0
8	OVFP	→	chOv + ov + OVFP + fp + MDCH	1.0
9	FPCS	→	fp + FPCS + cs + csCh	1.0
10	FPOV	→	fp + FPOV + ov + ovCh	1.0

Summary

GeoSyntax as a novel geological concept and technology evolved from the work of Griffiths (1989, 1990); Griffiths et al. 1992) and Duan et al. (1996, 1999, 2001a, b) who successfully demonstrated 1D syntactic interpretations of logs and generation of conditional simulations of simple 2D parasequences using syntactic techniques. This initial work further evolved at CSIRO (Hill and Griffiths 2006, 2007, 2008, 2009) and Sinopec (Duan 2017) to the point where it can be used for 3D applications in both forward and inverse modelling.

The computer programs and reports resulting from the CSIRO research can be accessed from the following websites.

Geotechnics

Pejman Tahmasebi

College of Engineering and Applied Science, University of Wyoming, Laramie, WY, USA

Definition

Geotechnics is the science of application of applied geology and mechanics for the problems related to the earth's surface or near-surface. As such, their target materials are categorized into two groups: soil and rock. Soil is considered as loose materials and sediments. Also, soil can be broken into pieces easily. Unlike soil, rock materials are very rigid materials, and the strong bond between grains can be found in the cohesion and molecular forces. The science generated in geotechnics can be useful in many natural phenomena and construction of facilities on the earth and beneath it.

Introduction

Geotechnics deals with geomaterials located on/near the surface of the earth. Geotechnics has influenced on several areas, such as rock mechanics which describes the properties and mechanics of rocks, soil mechanics that is concerned with soil's dynamic behavior, mechanics of materials, and kinematics of the soil. One often studies the soils and rocks since their behaviors are very different. Furthermore, all the materials that exist on the surface are not entirely soft or hard. In fact, most of the geomaterials can be categorized somewhere between soft and hard materials. Foundation science and engineering is another branch of geotechnics that deploys geology, rock mechanics, soil mechanics, and structural engineering to secure a structure from failure. The knowledge in geotechnics has also been used extensively to model large foundations to avoid the collapse of structures. In recent years, researchers have also considered environmental problems as well. This special attention has made new fields called geo-environmental engineering where the issues related to geotechnical engineering that affect the environments, such as groundwater quality, waste of industries disposal, nuclear waste disposal, etc. are studied. In summary, geotechnics is a combination of physics, mathematics, geology, environmental sciences, hydraulic, and mining engineering, to predict the behavior of soils or rocks.

All the ancient civilizations built many facilities on the surface or even underground. Coulomb, which is named as the leader of soil mechanics, was the first famous engineer that studied the stability of walls when they are under pressure. Coulomb's essay is the earliest soil mechanics study

published in 1776 by the Academy of Science. Collin was the first investigator that studies the stability of clay slope and the shear strength of clays, in 1846. Many researchers such as Darcy (1856), Rankine (1857), and Gregory worked in this field in the late eighteenth century. In the nineteenth century, the Swedish researcher, Atterberg, introduced the limits for clay soil, which is currently used by many engineers. In this period of time, the Swedish State Railways developed methods that can be used to calculate the stability of slopes. Moreover, they studied the subsurface techniques for soil sampling. In 1925, the German Professor, Karl Terzaghi who is named as the pioneer of soil mechanics, published his and the world's first textbook on soil mechanics (Terzaghi 1925). He wrote almost 250 technical reports and papers on soil mechanics. Professor Arthur Casagrande was a Harvard University professor between 1932 and 1969 who had an essential role in expanding and developing the science of geotechnics (Casagrande 1936a, b, 1948, 1965).

Geomaterials mostly contain pore spaces. As such, the total volume of a soil mass (V_t) consist of solid (V_s) and void (V_v). The void space can be filled by water (V_w) and/or air (V_a). This concept is shown in Fig. 1. Given the above parameters, the void ratio (e) is expressed as:

$$e = \frac{V_v}{V_s}. \quad (1)$$

The void ratio can vary from 0 to ∞ . For instance, the typical value for void ratio in sand samples is between 0.4 and 1.0. Similarly, the porosity (n) can be defined as:

Geotechnics, Fig. 1 Volumetric relationship for a soil using a phase diagram

$$n = \frac{V_v}{V_t} \times 100. \quad (2)$$

From Eqs. (1) and (2), one can write:

$$n = \frac{e}{1 + e} \quad (3)$$

$$e = \frac{n}{1 - n} \quad (4)$$

Also, saturation (S) can also be calculated using:

$$S = \frac{V_w}{V_v} \times 100. \quad (5)$$

In geotechnics, it is very common to use the unit weight (γ) instead of density g :

$$\gamma = \frac{W}{V} = \frac{\rho V g}{V} = \rho g \text{ [N/m}^3\text{]} \quad (6)$$

In small-scale problems where the soil particles are studied, the size of such instances is very important and can be used in computational modeling as input. Some of the available classifications are shown in Table 1. The behavior of the clay soil, for example, can be different based on the amount of water in the soil. When the amount of water increases, clay experiences four different stages, solid, semi-solid, plastic, and liquid. For each of the abovementioned stage, the behavior and general properties of the soil can be changed. Therefore, it is necessary to identify in which stage the clay and silt soil are found. This allows having an accurate estimation of its strength, other mechanical properties. To find the state of the soil, the Atterberg limit test can accurately characterize the stage that the soil is in White (1949). This concept is shown in Fig. 2.

As demonstrated in Fig. 2, the loss of water content will not cause a volume change before the SL level. By increasing the amount of water, however, the soil shifts from solid state to plastic level, which is called semisolid state. When the water content reaches the liquid limit, the soil changes the state from plastic to a liquid state. Using this information, one can calculate the Atterberg soil index, or the *plasticity index* (PI), by:

$$PI = LL - PL \quad (7)$$

The PI is the range between the plastic limit and liquid limit. If the PI is high, the soil has a high content of clay. The liquidity index (LI) is another index which can characterize the soil's consistency and is defined by:

Geotechnics, Table 1 Well-known particle size classifications

Organization	Particle Size (mm)			
	Clay	Silt	Sand	Gravel
AASHTO	<0.002	0.002–0.075	0.075–2	2–76.2
USDA (Minasny and McBratney 2001)	<0.002	0.002–0.05	0.05–2	>2
MIT	<0.002	0.002–0.06	0.06–2	>2

Geotechnics, Fig. 2 Demonstration the various states of soil based on the Atterberg limit. Here, the SL, PL, and LL represent shrinkage limit, plastic Limit, and liquid limit, respectively

$$PI = \frac{PL - W}{PI}. \quad (8)$$

In Eq. (8), W is the water content in the soil sample. The LI range is shown in Fig. 3. As can be seen, the state of the solid can be characterized by the value of the LL.

Another fundamental property of soil is their shear strength (S), which is expressed as:

$$S = \sigma \tan \theta + C, \quad (9)$$

where σ is the normal stress, θ is the friction angle of the soil, and C is the cohesion.

Research Path of Geotechnics

In recent years, environmental aspects are added to geotechnical application, which are most around water-soil interactions. However, there is still a gap in the geo-environmental numerical simulations. The computational power has increased in recent years, and it resulted in considering the effect of fluid to such modeling. The computational fluid

Geotechnics, Fig. 3 Various states of soil based on water content and LI

dynamic (CFD) is one of such methods that can help to simulate the fluid phase in geotechnical systems. For instance, groundwater pollution, which is one of the noticeable issues in geo-environmental science (Lopes and Quinta-Ferreira 2010; Wu et al. 2020), can be studied in this framework. Furthermore, to have more accurate simulations at the grain-scale, many investigators have applied the Lagrangian methods such as discrete element method (DEM) in geotechnical systems (Jiang et al. 2003; Ngo et al. 2014) wherein the particles are presented using spherical objects. Besides, these methods are coupled and a set of new CFD-DEM coupling can be used to represent both the solid and fluid phases, which can result in a more representative simulation (Guo and Yu 2017). This field of research still needs more investigation to better represent the morphology of particles and also provide a more feasible simulation when all such complexities are considered. More complex multiphysics simulation, such as those known as THMC (thermo-hydro-mechanical-chemical), can be developed for both small- and large-scale systems (Liu et al. 2014).

Conclusion

Geotechnics focuses on studying the mechanics of soils and rocks. The fundamental knowledge of this area was discussed. Due to the length limitation for this entry, all the necessary materials were not covered, but we restricted the topics to those through which one can study the behavior of soils. More interdisciplinary studies have been and will be conducted, and this topic can benefit various other fields, such as structural engineering, water resources engineering, hydraulic structures engineering, environmental engineering, mining engineering, etc.

Geothermal Energy

Katsuaki Koike and Shohei Albert Tomita
Department of Urban Management, Graduate School of Engineering, Kyoto University, Kyoto, Japan

Definition

The Earth contains a large amount of heat energy. The planet's interior temperature has been shown to strongly and linearly increase with depth at shallow depths, exceeding 1000 °C at the lithosphere-asthenosphere boundary (~100-km depth) following a general temperature gradient of 20–30 °C/km, and gradually increase in the asthenosphere, mesosphere, and core. The Earth's interior heat is transferred to the surface with a mean surface heat flux of 87 mW/m², which mostly (~80%) originates from the decay of radioactive isotopes (mostly ²³⁵U, ²³⁸U, ²³²Th, and ⁴⁰K), and the remainder is mainly from primordial cooling (Turcotte and Schubert 2014). This heat production drives mantle convection and resultantly plate motion.

The heat in the shallow crust within several kilometers depth can be used as geothermal energy for electric power generation, agriculture, aquiculture, and recreation. The importance of geothermal energy has recently increased in terms of renewable energy-based power generation owing to its high power output, high operation rate, and low CO₂ emissions. A power-generating turbine is rotated by high-pressure steam that originates from a hydrothermal fluid, which is a mixture of water and gas originated generally from meteoric water heated by an interior heat source (e.g., deep magma chamber) or injection water through hot rocks. These fluids are stored in reservoirs that are generally formed by permeable and continuous fractures under a caprock layer. Heat sources, fluids, and fractures are therefore fundamental elements within high-potential geothermal energy zones.

The main properties of a fluid include temperature, pressure, and flow pattern, which can be estimated using numerical simulations by adopting an optimal hydrogeologic model. The subsurface and surface temperature distribution is an essential property because it provides basic information regarding these three elements. Fluid path fractures and heat sources can be detected using remote sensing technology to

measure geologic structural and mineralogical features and surface displacement. Mathematical geologic methods have been applied to improve the modeling accuracy of fluid flow, temperature distribution, fracture systems, and regional geothermal systems caused by a heat source. An example of subsurface temperature modeling is outlined in Fig. 1.

Subsurface Temperature Modeling

Application of Geostatistics

The three-dimensional temperature distribution is the most fundamental piece of information for specifying large geothermal energy zones. The temperature distribution can be estimated or simulated by applying geostatistics using well-logging or bottom-hole temperature data, which are obtained in geothermal or petroleum/gas resources exploration operations and recognized as a regionalized variable. One precaution that should be considered when using this spatial modeling approach is the physics that controls the temperature-change pattern with depth. The patterns are generally classified into two types depending on whether the heat

Geothermal Energy, Fig. 1 Example of temperature modeling for the Hoho geothermal field in southwestern Japan using well logging data from different bottom depths. (Modified from Teng and Koike (2007)). (a) Topography and well location with lengths of 80–3300 m. (b) Schematic temperature profiles of conductive and convective thermal types. (c) Temperature model integration showing high-temperature

zones (>150 °C), a geologic model composed of eight formations, and large-magnitude fluid flow vectors for imaging the geothermal system. A NW-SE vertical cross-section passing through two hot springs along the dashed line in (c) schematically shows the downflows of meteoric waters and shallow oval-shaped reservoirs

is transmitted via conduction or transferred via fluid convection. A conductive pattern involves a linear increase of temperature with depth, whereas a convective pattern bears an inflection point that separates the linear increase with depth at shallow depths and the nearly constant temperature at greater depths. These temperature-depth trends result in temperature datasets to be non-stationary variables. Another precaution to consider is that the temperature data are quite sparse at great depth, and suitable measures are therefore required to extrapolate shallow data for temperature modeling at reservoir depths or deeper.

One effective measure is to approximate the temperature-variation pattern using a polynomial and kriging with external drift is then applied by regarding the polynomial as a trend. A global linear trend (i.e., constant geothermal gradient) is applicable in cases when most of the data follow a conductive pattern type over a sufficiently wide area (e.g., hundreds of thousands of km²) (Agemar et al. 2012; Tian et al. 2015). Convective patterns dominate the well-logging data of geothermal fields with high-output power stations. One example is the world-famous, Wairakei geothermal field in New Zealand in which the trend was approximated well by a third-order polynomial (Sepúlveda et al. 2012). Previous studies have demonstrated the effectiveness of incorporating this trend because the increased temperatures and hot zones are estimated in deeper zones beyond the well bottoms.

In addition to temperature data, geologic column data are also useful for constructing geologic models, typically by transforming column data into binary data (i.e., 1 for a selected rock type; 0 for other types). The spatial modeling of these binary datasets provides information regarding the rock type that is most probable to occur at a given location, and can thus be applied to construct geologic models. The superimposition of the estimated temperature distribution on a constructed geologic model enables the interpretation of fault structures, fault permeability, main fluid flow paths, flow patterns (up, down, or lateral flow), and the location, configuration, and rock type of a reservoir with high temperatures and dominant upflows, as demonstrated for the Wairakei field (Sepulveda et al. 2012) and Hoho field in Japan (Teng and Koike 2007).

Application of Machine Learning

Machine learning techniques are also applicable to logging data to obtain the temperature distribution. A deep neural network (DNN) is a typical method that uses the relationship between the data location and measured temperature. One measure to evaluate the DNN capability is the extrapolation accuracy of logging data because deep logging data are generally limited. Network learning is repeated until the total difference between the network outputs and data values are acceptably small, which is the chief factor of the learning

criterion. Multiple factors can also be incorporated into the learning process as constraints. A thermal-type semi-variogram is one example that assigns 0 or 1 to a drilling site of either conductive- or convective-type patterns and produces a binary dataset. This constraint can be used to locate high-temperature zones and derive a convection fluid pattern by honoring the spatial correlation of the thermal type (Koike et al. 2001). Other methods, such as XGBoost and Random Forest, are also powerful and accurate tools for temperature modeling. These methods can predict temperatures at great depths by extrapolation and generate geothermal gradient maps to specify high potential resource zones with a large gradient using a dataset of bottom-hole temperatures (Shahdi et al. 2021).

Remote Sensing Applications

Outline of Remote Sensing

Remote sensing (RS) technology can provide extensive and repeated Earth surface observations in a short time period using electromagnetic waves sensed through optical and microwave sensors onboard satellites, airplanes, and unmanned aerial vehicles. The reflectance of surface materials in visible, near-infrared, and short-wave infrared regions and their radiance in infrared thermal region are the targets of optical sensors, whereas scattering is the main phenomenon for the longer wavelengths of microwave sensors. RS can effectively identify geothermal manifestations (e.g., hot springs, fumaroles, and hydrothermal alteration) over a wide area, which can be used to identify the presence of an underlying latent geothermal resource. RS applications to geothermal resource exploration are typically classified into four categories, as outlined in Fig. 2.

Surface Temperature Estimation

The most traditional application is the measurement of surface temperature based on Planck's law to detect high surface temperature zones. This law describes the spectral radiance B (Wm⁻²μm⁻¹sr⁻¹) of a black body of wavelength λ (m) of an electromagnetic wave at absolute temperature T (K) according to:

$$B = \frac{c_1 \lambda^{-5}}{\pi [\exp(c_2 / \lambda T) - 1]}$$

where c_1 and c_2 are constants derived from the Planck and Boltzmann constants, respectively ($c_1 = 3.7418 \times 10^{-16}$ Wm⁻², $c_2 = 1.4393 \times 10^{-2}$ mK). The surface temperature T_s can be calculated from B in the thermal infrared region and the surface material emissivity. T_s is used to calculate the radiant heat flux Q_r (Wm⁻²), which is proportional

Geothermal Energy, Fig. 2 Schematic diagram of RS applications to detect geothermal energy-related surface features. These include thermal infrared image analysis of surface temperatures and the extraction and mapping of hydrothermal alteration minerals using reflectance

absorption, lineament-based fracture characterization, and topographic change mapping by D-InSAR. These application targets are detected by the development of permeable fractures acting as fluid paths, the upflow of hot fluids, and the existence of deeply seated heat sources

to T_s^4 following the Stefan–Boltzmann law (Vaughan et al. 2012), and to assess geothermal energy.

Due to several factors such as atmospheric and topographic effects, heterogeneity of emissivity may vary over a short distance, and different observation dates, RS-based T_s values typically do not match with in situ measurements. By combining in situ measurements, T_m values, as hard and conditioning data, and RS-based T_s values as soft data, T_s can be corrected to match T_m using geostatistical techniques. The corrected T_s (T_s^*) is given as:

$$T_s^*(\mathbf{u}) = T_m^k(\mathbf{u}) + [T_s(\mathbf{u}) - T_s^k(\mathbf{u})]$$

where $\mathbf{u}$ is the location, $T_m^k(\mathbf{u})$ is the kriging estimate at $\mathbf{u}$ using the in situ measurement data, and $T_s^k(\mathbf{u})$ is another kriging estimate using T_s at the data location.

Another example is to downscale the T_s distribution from coarse- to fine-resolution images using geostatistics (Poggio and Gimona 2013). This approach can be used to effectively reveal the T_s distribution at a finer scale and shorter time interval than the actual data because the observation time intervals of fine images are substantially longer than those of coarse images.

Detection and Mapping of Hydrothermally Altered Minerals

A second traditional application is the detection and mapping of hydrothermal alteration minerals using reflectance band data (i.e., of a selected wavelength range). The analysis of alteration minerals can be used to indicate the temperature and chemical properties, typically acidity of the hydrothermal fluids that generate certain mineral types. For example, water-rock interaction leads to the formation of illite at

approximately 200 °C and Wairakite at approximately 300 °C. The abundance of high-temperature alteration minerals on the Earth's surface suggests the high potential of geothermal energy.

An effective indicator for mineral detection is the wavelength and depth of the reflectance absorption in the visible to short-wave infrared region because this feature is caused by specific ions (Fe^{2+} , Fe^{3+} , OH^- , CO_3^{2-}) and water molecules (H_2O), which are generally contained in hydrothermal alteration minerals. This absorption is enhanced by the band ratio. The simplest measure is described by A/B or $(A/B) \times (C/D)$, where B and D are the low reflectance values of the absorption bands and A and C are the high reflectance values of the reference (i.e., non-absorption) bands. Other band-ratio equations are possible as long as the equation value increases with increasing reflectance absorption at one, two, or more bands. The band-ratio equation for a mineral is termed its mineral index (e.g., alunite index). The band ratio only shows the possibility of a target mineral and has no definite criterion of its value for a mineral's presence or absence. Spectral matching with reference data of standard minerals is another standard method to discriminate minerals, for which machine learning and LASSO logistic regression analysis have been recently adopted to increase the accuracy (Shim et al. 2021).

A critical issue that reduces a mineral's detection accuracy is a limited number of bands in a multispectral sensor image. For example, the number of Terra ASTER sensors for the most widely used imagery in geological studies is nine. In contrast, hyperspectral sensors have hundreds of bands with high spectral resolution, which can be used to unravel the absorption features of a target mineral. However, the availability of hyperspectral images is quite limited in certain areas. Because multispectral images cover almost the entire Earth's surface, they have the possibility to simulate hyperspectral images. The pseudo-hyperspectral image transformation algorithm (PHITA: Hoang and Koike 2017) is a method that can meet this demand. PHITA combines band reflectance data between multispectral and hyperspectral images using a multiple linear regression model as:

$$\rho_{ij}^H(\lambda) = \beta_{0i} + \sum_{k=1}^m \beta_{ki} \cdot \rho_{kj}^M(\lambda) + \varepsilon_{ij}$$

where $\rho_{ij}^H(\lambda)$ represents the reflectance of the hyperspectral band i and pixel j , β_{0i} is the intercept of i , $\rho_{kj}^M(\lambda)$ is the reflectance of multispectral band k at j , β_{ki} is a regression coefficient between k and i , ε_{ij} is a residual, and m is the number of given multispectral bands. Geologic information, such as the mineral index or lithotype, can be incorporated into this equation as an auxiliary parameter to increase the transformation accuracy because reflectance spectra differ for different minerals and rocks. This feature can thus serve as

conditioning for the transformation. More advanced methods to correlate band reflectance data between multi- and hyperspectral images (e.g., machine learning) are applicable instead of linear regression. PHITA has demonstrated an increased detection accuracy of hydrothermal alteration minerals, such as muscovite and calcite, from multispectral images with the same degree of hyperspectral imaging (Hoang and Koike 2018).

Lineament-Based Fracture Characterization

Lineament extraction from optical and microwave sensor images and digital elevation models (DEMs) is another application from the aspect of fluid-path fractures. Lineament is a linear or slightly curved topographic feature that appears in images and shaded DEM images. Its geologic importance arises from the fact that lineaments are generally caused by continuous rock fractures, including faults. Lineaments have therefore been used to characterize fracture distributions in terms of direction, length, and density. In addition to these planar distribution features, the orientation (strike and dip) of dominant fractures can also be estimated by concatenating several lineaments with a similar direction that are located on almost the same line or gentle curve using vector analysis to determine the relationship between lineament direction and normal directions of the slopes in the lineament path (Koike et al. 1998).

A primary purpose of lineament extraction for geothermal studies is to specify permeable fractures that act as pathways of ascending fluid flow from a reservoir. One example is the correspondence of high-density zones of lineaments extracted from synthetic aperture radar (SAR) images with surface features of alteration, mud pools, and hot springs (Saepuloh et al. 2018). For comparison, a fine-scale density map is produced by kriging of the density data defined in a large (1×1 km) cell and assigned to the cell center.

Gas geochemistry using soil gas samples is a particularly effective tool to locate upflow zones. One essential component is radon-222 (Rn), which migrates through permeable fractures. However, the number of sampling sites is usually limited in a given study area because of topographical, temporal, and cost constraints. Detailed Rn concentration features can therefore not be clarified over most study areas. One solution is the application of cokriging using Rn concentration data and lineament density data as the primary and secondary variables, respectively. The effectiveness of this method has been confirmed by the good agreement of high Rn concentration zones with geothermal features (Heriawan et al. 2021).

Continuous Mapping of Topographic Change by D-InSAR

Differential interferometric SAR (D-InSAR) is a technique that measures the topographic change that accompanies crustal deformation, which occurs between image acquisition

dates and is typically caused by earthquakes, volcanic eruptions, landslides, and subsidence. This change is expressed as the displacement velocity (mm/year) from the D-InSAR processing of several image pairs. The applications of D-InSAR to geothermal studies can be categorized into two themes. The first is for resource management. Reservoir pressures are reduced by the overuse of geothermal fluids and insufficient return of fluids to the reservoir, which resultantly leads to surface subsidence. Topographic change monitoring, therefore, contributes to sustainable resource development by preventing the overuse of fluids. The second category is the detection of high potential zones of geothermal energy. Regional topographic change can also be induced by magmatic activity following an increase or decrease of pressure in a deep magma chamber. Geothermal reservoirs form above magma chambers. Areas that intermittently show large topographic changes that are unrelated to landslides may therefore reflect the presence of an active magma chamber that yields large geothermal energy.

One critical issue of D-InSAR is that topographic changes are only detected in pixels with high coherence between an image pair. High coherence cannot be obtained in vegetated areas because the scattering properties of plant surfaces are continuously changeable by growth and meteorological factors. Accordingly, pixels that show a displacement velocity are sparse over a SAR scene. Kriging methods can compensate for undetected displacements in the low-coherence pixels and clarify the overall displacement velocity (Yaseen et al. 2013). A displacement velocity map in a geothermal field produced by kriging contributes to identify the geologic structural controls on topographic change, locate advanced hydrothermal alteration zones, and estimate the sensitivity of a reservoir to production and fluid reinjection (Sabrian et al. 2021).

Fluid Flow Simulation

After constructing a conceptual model of a geologic structure, numerical simulations are implemented to unravel the fluid flow pattern and estimate the power generation by solving the balance equations of mass, momentum, and energy. Because flow is generally laminar and slow, it tends to follow Darcy's law. This simulation consists of three steps: data interpretation; model calibration; and forecasting (Franco and Vaccaro 2014). The first step is to build a reliable numerical model using geological, geophysical, and geochemical data analyses. The numerical model is then refined and its accuracy iteratively improved in the second step by two matchings of the natural state and production history. In the natural state matching, the thermophysical parameters (e.g., permeability, thermal conductivity, porosity, and specific heat capacity) and boundary conditions are determined by matching with the

well-logging temperature and pressure data over long simulation times (typically 10^5 – 10^6 years) for model convergence. Figure 3 depicts an example of the first and second steps. For geothermal power generation areas, the natural state model is iteratively improved by mainly matching with the history data of temperature and mass flow rate with production and reinjection. The third step is simulation for future geothermal fluid development scenarios.

The correct incorporation of a fracture system is essential in the numerical models owing to its role as a path or barrier of fluid flow. Fracture systems in geothermal reservoirs are generally simplified and representatively expressed using a dual-continuum model (DCM) to improve the computational efficiency, and subdivided into dual or multi-porosity models, a dual-permeability model, and a more general multiple interaction continua approach (MINC) (Wu 2016). The DCM treats the matrix and fracture system as two separate continua over the model domain. The MINC can more rigorously handle transient flow between fractures and matrix by subdividing the matrix system in each grid block into a sequence of nested subblocks.

STAR, TETRAD, and TOUGH2 are geothermal reservoir simulators that can handle multiphase and multicomponent fluid flows (O'Sullivan et al. 2001). These simulators were developed to incorporate chemically reactive flow, inverse modeling of thermophysical parameters for model calibration optimization, and the coupling of thermal, hydraulic, mechanical, and chemical properties.

Summary

The potential of geothermal energy for power generation can be evaluated using subsurface and surface properties. The temperature distribution with depth is the most representative subsurface feature, which can be modeled by applying geostatistical and machine learning methods to well-log and bottom-hole temperature datasets. The model should consider the physical laws of heat transfer (conductive- versus convective-type) which govern the temperature-change pattern with depth. This behavior is indispensable because it forms the basis of the temperature trend and allows the temperature data to be used as a non-stationary variable. The incorporation of the thermal type enables the temperature to be estimated in deep regions below the well bottoms. The integration of temperature data and geologic models is effective for interpreting fault systems, fluid flow paths and patterns, and the location and configuration of a reservoir.

The principal surface properties include temperature, hydrothermal alteration minerals, fracture systems, and topographic change, which are detected based on the RS analysis of thermal-infrared images, reflectance-absorption based spectral features, lineaments, and D-InSAR, respectively.

Geothermal Energy, Fig. 3 Example of a calculation model, simulation result, and verification for a seafloor hydrothermal vent area. (Modified from Tomita et al. (2020)). (a) Division of area by Voronoi cells and settings of boundary conditions on the heat source, discharge, and a conduit zone. Only a caprock layer and vertical conduit zone are

shown. (b) Vertical cross-section showing the model size, buffer area, cell configuration, geologic structure composed of four elements, and boundary conditions. (c) 3D view of iso-temperature surfaces and fluid flows (arrows) with seafloor drillings (red lines). (d) Comparison between calculated and measured temperatures at two sites

Although these properties are indirect indicators of geothermal energy, they can provide valuable information regarding upflow zones at high temperature, the development of permeable fractures, and the location and extent of heat sources. Geostatistical methods can be applicable for the conditioning of in situ data for image analysis and the detection of surface displacement over an image scene. The detection accuracy of alteration minerals and permeable fractures can be increased by downscaling the reflectance spectral data using auxiliary geologic parameters and the co-kriging method to include a combination of lineament and geochemical data, respectively.

In addition to these mathematical geologic applications, subsurface physical properties modeled using geophysical methods are essential for imaging geothermal structures. Resistivity is the most common parameter measured by magnetotelluric (MT) and audio-frequency MT surveys. The combination of physical properties applied using the above methods increases the assessment accuracy of geothermal energy potential and provides a deeper understanding of geothermal systems.

Definition

Global and regional climate models are formalized descriptions of the climate system, which differ by the resolution (generalization) or modeling step. The result of the simulation is global, regional (or local) distributions of climate data, with a spatial resolution of 500–100 or 10–50 km, respectively. Accordingly, these models refer to the impact of the processes of different scales and origins in the atmosphere, ocean, and land surface.

Introduction

The rapid development of computational methods in recent decades has led to the transformation of applied mathematics in geosciences into a successful tool for solving many important tasks (Sagar et al. 2018): from natural resources exploration to meteorology.

Among other problems connected with human well-being and security, there are several complex tasks, where the application of mathematical geosciences is required, such as support of sustainable development, climate change adaptation, disaster risk reduction or reducing vulnerability, and enhancing the resilience of ecosystems and communities.

Solving these tasks should be based on the multiscale climate predictions, which requires the development of climate models – a direct task of mathematical geoscience.

Climate: Basic Approaches to Analysis

When we speak about climate, usually we focus on the slowly varying aspects of the atmosphere-hydrosphere-land surface system (Miller 2019). Climate may be usually described by average parameters and variables of the climate system during the periods of a month or more, considering the time variability of parameters and variables. Classification of climatic types usually include the spatial variation of used averaged variables. The climate description concept has substantially evolved with the broadening of the understanding of the key climate-determining processes and its variations: covering more than annual local variations of averages of surface temperature and precipitation.

From the viewpoint of sustainability, usually, we are interested to study climate change and climate anomalies.

Climate anomaly may be described as the quantitative difference between the average decadal climatic parameters, and the climatic parameters during separate month/season.

At the same time, the long-term systematic statistics trends of the climatic parameters (such as temperature, pressure, or winds) should be enough sustained over a period of several decades. Climate change may be caused by the natural external forcing (for example, the changes of solar emission, or changes in the Earth's orbital elements), by natural internal processes in the climate system, or anthropogenic forcing.

To understand the behavior and variations of the climate system the climate predictions are usually applied.

Climate prediction is the calculation-based prediction of different parameters and aspects of the climate system during determined future time period. Climate predictions are usually presenting as the set of interconnected probabilities of anomalies of climate variables (temperature, precipitation, etc.), for the period of several seasons. Also, the term “climate projection” is now commonly used for long-term predictions rather than “climate prediction,” because described scenarios have a higher uncertainty and less specificity (for example, “projection” is preferentially used in analysis of climate reactions to variations of land use).

A climate system – the system, comprising the atmosphere, hydrosphere, lithosphere, and biosphere, interrelation and external forcing reaction which determine the planetary climate, and physical, chemical, and biological processes in these components define the interactions among the components of the climate system (Trenberth 1992).

Modeling is the usual method for analysis of climate system behavior (Howarth 2017). A model is a tool for simulation and simulation-based prediction of the behavior

of the dynamic systems, for example, the Earth's atmosphere. Varied models can be based on varied approaches: subjective heuristic methods, statistics, simplified physical systems, analogy, but now this term is most commonly applied to numerical models, wherein different models require varied methods of model calibration (Howarth 2017), such as different approaches to adjusting of the numerical model parameters to optimize the agreement between observed and simulated data (model's predictions).

Modeling: Tools and Approaches

Modern approaches to the analysis of climate system behavior are mainly based on the varied coupled ocean-atmosphere circulation models (Jursa 1985).

Coupled ocean-atmosphere general circulation model is a climate system model that includes coupled interacting atmospheric and oceanic components. The atmospheric and oceanic components in many cases presented as the general circulation models in global or regional scale. These types of models are used for study of the climate system response to time variations of external and internal forcing parameters, such as the atmospheric greenhouse gases concentration. Key models' control parameters include surface pressure, horizontal components of velocity, temperature and water vapor, solar and terrestrial short, long wave, infrared radiation, convection, Albedo, hydrology, and cloud cover.

Usually, such types of models include also geosphere-biosphere components, describing water and carbon balance inland and ocean's ecosystems.

A key component of climate models is the atmosphere models (Jursa 1985). The atmosphere model is a formal theoretical representation of the atmosphere, first of all, the vertical temperature distribution.

Now there are numerous atmosphere models used for analysis of climate system and predictions of its behavior: adiabatic atmosphere, homogeneous atmosphere, isothermal atmosphere, thermotropic model, equivalent barotropic model, barotropic model, and standard atmosphere. These models are traditionally used in climate system analysis.

Adiabatic atmosphere (or “dry-adiabatic atmosphere,” “convective atmosphere”) is a traditional widely used atmosphere model with a dry-adiabatic lapse rate along the vertical axis, and the pressure in the adiabatic atmosphere decreases with height. Practically, such a condition is never truly observed, and also this description is not correct enough, because “adiabatic” represents a process, not a condition.

A homogeneous atmosphere is a hypothetical atmosphere representation, in which the density is constant with height. In this atmosphere model the lapse rate of temperature is presented as the autoconvective lapse rate and is equal to g/R (approximately $3.4^{\circ}\text{C}/100\text{ m}$), where g is the acceleration of

gravity, and R is the gas constant. A homogeneous atmosphere has a finite total thickness, determined as $R_d T_v / g$ (where R_d is the gas constant for dry air, and T_v is the virtual surface temperature). For a surface temperature of 273 K, the vertical extent of the homogeneous atmosphere is approximately 8000 m. Formally, a homogeneous atmosphere model is similar to the adiabatic atmosphere.

Isothermal atmosphere (also called “exponential atmosphere”) is an idealized atmosphere representation in hydrostatic equilibrium. In this model the temperature is constant with a height, and the pressure decreases exponentially.

The thermotropic atmosphere model is an atmosphere model for numerical forecasting, in which the simulated parameters are the height of the constant-pressure surface (usually 500 mb) and the temperature (usually the mean temperature). In this model the quasi-geostrophic approximation is applied, and the thermal wind is assumed height-constant. Using this model, surface prognostic maps can be constructed.

The equivalent barotropic atmosphere model is an advanced representation of the barotropic model. In this model the wind height variation is averaged, based on the assumption that the thermal and geostrophic wind has the same directions at all heights. The resulting model is simulating the geostrophic stream function as the single-parameter representation of the barotropic vorticity equation. Due to its simplicity, the equivalent barotropic model is the very popular barotropic model for numerical forecasts using real observation data.

Barotropic atmosphere model is a designation of the cluster of atmosphere models, which is characterized by the following conditions: when pressure and temperature surfaces coincide; the vertical wind shear is absent; the vertical motions are absent; the horizontal velocity divergence is absent; and the vertical component of absolute vorticity is conserved. There are two usual classes of the barotropic models: the nondivergent and the divergent barotropic model (which is also called the “shallow-water equations models”); the simplest form of the barotropic model is based on the barotropic vorticity advection equation. Barotropic atmosphere models cannot predict the behavior of weather systems, because there are no vertical variations or thermal advection processes in this type of model.

The standard atmosphere is a formal description of hypothetical vertical distribution of the determined set of parameters: atmospheric temperature, pressure, and density. These parameters, by common agreement, are assumed as the representative for instrumental purposes: altimeter calibrations, aircraft performance calculations, aircraft and missile design, ballistic tables, etc. (Jursa 1985).

In this model, the air is assumed to obey the perfect gas law and the hydrostatic equation. These relations define together

interconnected temperature, pressure, and density vertical variations. It is also assumed that the air contains no water vapor and that the acceleration of gravity is constant with height (so, for representing the measure of vertical displacement a particular unit of geopotential height may be adopted in place of a unit of geometric height, because these two units are numerically equivalent). The current standard atmosphere model was adopted in 1976 and is a slight modification of 1952 model adopted by the International Civil Aeronautical Organization (ICAO), which, replaced the NACA Standard Atmosphere (or US Standard Atmosphere) of 1925. This model assumes the following parameters for sea level: temperature is 288.15 K (15°C), the pressure is 101 325 Pa (1013.25 mb, 760 mm of Hg, or 29.92 of Hg), density is 1225 g m⁻² (1.225 g L⁻¹), and mean molar mass is 28.964 g mole⁻¹.

The assumptions about parameters and constants in the standard atmosphere model are the following: zero pressure altitude is 760 mm high of mercury column (this pressure is equal to 1.013250×10^6 dynes cm⁻² or 1013.250 mb, and is known as “one standard atmosphere” or “one atmosphere”), the temperature at zero pressure altitude is 15°C or 288.15 K, the gas constant for dry air is 2.8704×10^6 ergs gm⁻¹K⁻¹, the ice point at the standard atmosphere pressure is 273.16 K, the density at zero pressure altitude is 0.0012250 gm cm⁻³, the lapse rate of temperature in the tropopause is 6.5°C km⁻¹, the pressure altitude of the tropopause is 11 km, the temperature at the tropopause is -56.5°C, and the acceleration of gravity is 980.665 cm s⁻².

The ARDC (Air Research and Development Command) Model Atmosphere, 1959, extended the above standard as follows: the lapse rate from 11 km to 25 km is 0°C km⁻¹, the lapse rate from 25 km to 47 km is +3.0°C km⁻¹, and temperature at 47 km is +9.5°C, the lapse rate from 47 km to 53 km is 0°C km⁻¹, the lapse rate from 53 km to 75 km is -3.9°C km⁻¹, and temperature at 75 km is -76.3°C, the lapse rate from 75 km to 90 km is 0°C km⁻¹, the lapse rate from 90 km to 126 km is +3.5°C km⁻¹; the temperature at 126 km is +49.7°C (molecular-scale temperatures), the lapse rate from 126 km to 175 km is +10.0°C km⁻¹; the temperature at 175 km is 539.7°C (molecular-scale temperatures), the lapse rate from 175 km to 500 km is +5.8°C km⁻¹; the temperature at 500 km is 2424.7°C (molecular-scale temperatures).

In the contemporary version of this model, a standard unit of atmospheric pressure, the 45° atmosphere, is defined as that pressure of a 760-mm mercury column at 45° latitude at sea level at temperature 0°C. This is a unit recommended for meteorological use.

So, as we can see, the existing complex multicomponent models mainly are oriented to the analysis of the climatic system as a whole, on the global scale, and need to be reduced to subregional or especially local scales in varied ways.

Global Versus Local

Classic climatology traditionally operates on macro-, meso-, and microclimate terms to analyze varied scales specific of the climatic parameters (Miller 2019; Arias 1942).

Macroclimate is the general large-scale climate of a large area (for example, country), as distinguished from the mesoclimate and microclimate.

Mesoclimate is the climate of a natural region of a relatively small extent (for example, valley, forest, plantation, and park). Due to insignificant elevation and exposure variations, the climate may not be representative of the general regional climate.

A microclimate is the fine climatic structure of the near-surface air space that extends from the Earth surface to a height where the effects of the underlying surface no longer can be distinguished from the general local climate (mesoclimate or macroclimate). The microclimate varies with and is superimposed upon the larger-scale climate conditions. There are some formal limits for determination of the thickness of the microclimatic layer concerned: in the general case, four times the height of surface features define the level where microclimatic layers disappear. However, in many cases this layer thickness should be considered as variable. There are many different classes of microclimate depending on the types of the underlying surface. Depending on land cover and land use types detalization/typization, several microclimate classes may vary from 7 up to 37 and more. Currently, the most studied and applicable types of microclimates are the “urban microclimate” (affected by street paving, buildings, industrial construction, air pollution, inhabitation, etc.), and the “vegetation/plant microclimate” (conditioned by the complex nature of interactions in the airspace over the vegetation landscapes).

At the same time, such an approach is substantially limited in numerical modeling, because the model resolution is limited and depends on the modeling step, e.g., of available input data, topology, modeling method, etc.

The main part of existing models based on the finite difference method uses non-rectangular grids with a variable resolution between 1 and 5 degrees in latitude or longitude (Collins et al. 2004). Most usable models have resolution 3.75 in longitude and 2.5 degrees in latitude (Collins et al. 2004), 1.875 degrees in longitude and 1.25 in latitude, and 1.25 in longitude x 0.83 degrees in longitude (Shaffrey et al. 2017). So, these are mainly global models to analyze macroclimatic parameters.

At the same time many important socioecological tasks, such as local community resilience, ecosystems’ vulnerability, agricultural production analysis, etc., require analysis of climatic parameter distribution with a resolution of at least 10–30 km (meso- and microclimatic analysis). In such a situation, application of varied algorithms of data regularization and downscaling is needed to obtain the regional,

subregional, and local distribution of climatic parameters instead of global.

Regularization is a formal technique for selecting the eligible level of model complexity (generalization) to give better model predictivity. This procedure is applied, in particular, for reducing topology effects and impact of non-rectangular grids. The resulting data has regular spatial and temporal distribution in a required coordinate system with the required accuracy and controlled reliability.

Downscaling is a procedure to obtain high-resolution information from low-resolution variables.

Application of regularization and downscaling procedures make it possible to analyze subregional and local climate parameters anomalies and changes. Local change is the change in a variable during a specified interval of time at a fixed point in the coordinate system in use. It is used to analyze the impact of spatially distributed processes on the local scales (microclimatic analysis).

However, as a result of the application of regularization and downscaling procedures, such regional/local distributions of parameters can be obtained that will not correspond to global models.

Summary and Conclusions

The investigated climate system is characterized by deep uncertainties, depending on the spatial and temporal scales (Caers 2011). At the same time, the existing models of the climate system are complex multicomponent, heterogeneous models based on different approaches and tools. In this context, the following should be noted.

First, regularization and downscaling procedures should not be based on simple averaging, but on complex statistical algorithms, and should take into account additional data, so as not to lose important local variations. So, in essence, local distributions and global models may be recognized as methodologically different cases.

Second, traditional approaches to the assessment of model accuracy, correctness, reliability, and usability cannot be applied to climate models and need to be modified depending on the type of model, scale, problem to be solved, and types of data used.

Understanding of the methodological and methodological context, as well as the existing limitations, will allow correctly building a hierarchy of climate models by spatial resolution and adequately solving the required applied tasks.

Biography

Michael Frank Goodchild (born February 24, 1944), a British American, is a highly decorated academic and scientist. He is an Emeritus Professor of Geography at the University of California, Santa Barbara (UCSB). He joined UCSB in 1988 as part of the establishment of the National Center for Geographic Information and Analysis (NCGIA), which he directed for over two decades, after 19 years at the University of Western Ontario, including 3 years as chair. In 2008, he founded the UCSB Center for Spatial Studies, where he held until 2012 the Jack and Laura Dangermond Chair of Geography and oversaw the activities of the center as the director. His research and teaching interests focus mainly on issues in geographical information science (GISci), including uncertainty in geographic information, discrete global grids, and volunteered geographic information. He directed or codirected several large funded projects, including the NCGIA, the Alexandria Digital Library, and the Center for Spatially Integrated Social Science. He moved to Seattle upon superannuation in 2012 and currently holds part-time positions as Research Professor at Arizona State University and as Distinguished Chair Professor at Hong Kong Polytechnic University. He lectures widely on the popular topic of “Science of Where.”

He had his undergraduate in physics from the Downing College of the Cambridge University in 1965, followed by his Ph.D. in geography from the McMaster University, Canada, in 1969. As a doctoral student, he rediscovered 20-kilometer-long Castleguard Cave in Canada. His most powerful work has involved research on GISci (aka GIS). He is widely credited with coining “volunteered geographic information” and other models for the production of geographic information. He has been a pioneer in the areas of GISci (Goodchild and Mark 1988, Longley et al. 2011), science, and technology, and has been known the world over for setting GISci foundations in the early 1990s as the science of collecting, analyzing, digitizing, and using geographic data. He has published over 550 books and articles. The way he led research involving quantitative techniques such as fractal geometry, geostatistics, and spatial statistics for managing and analyzing the very large databases, now called “Big Data,” that result and handling uncertainty in the data is remarkable. He introduced theoretical frameworks of fractals (Goodchild 1980), geostatistics (Goodchild 1980, Goodchild and Lam 1980), and spatial statistics (Goodchild and Klinkenberg 1993, Goodchild 2008, 2009) to address the issues related to accuracy and uncertainty (Goodchild 1991) in all of these areas. His interest is in discrete global grids, a set of methods for representing variation over the curved surface of the Earth and implemented in tools such as Google Earth. Of late, he is also spearheading new ways of mass collection and analysis of geographic data with crowdsourced

mapping and citizen science projects, wayfinding, and urban mobility, including the long-term impacts of connected and autonomous vehicles.

Several books and edited volumes that Professor Goodchild published are of huge value not only for the GIS and geography communities but also for the mathematical geoscience community as most of the temporal data handled by mathematical geoscientists are spatial in nature. I am one of those large pools of researchers who benefited a lot from working through his publications associated with spatial data sciences while introducing mathematical morphology to address various challenges, encountered in (geo)spatial data science, such as information retrieval, information characterization, quantitative information reasoning, simulation, modeling, and spatiotemporal visualization.

Goodchild received many awards and honors from top-notch academic societies and associations. To mention a few, he has received the Prix Vautrin Lud (2007) – informally known as the “Nobel Prize of Geography” – and the Royal Geographical Society’s Founder’s Medal (2003), CODATA Prize (2012) from the Committee on Data for Science and Technology of the International Council for Science, and International Spatial Accuracy Research Association’s Peter A. Burrough Medal (2012). He has been elected as a member of the American Academy of Arts and Sciences (2006), the US National Academy of Sciences (2002), and as a fellow or foreign member of the Royal Society of London (2010), British Academy (2007), and Royal Society of Canada (2002). He has received honorary doctorates from many universities, including, to mention a few, Ryerson University, McMaster University, Keele University, and Université Laval.

The Goodchild’s “Science of Where” has attracted many young-generation students and researchers, and they all see him as one of the founding fathers of the GISci and a role model.

Gradstein, Felix

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Fig.1 Prof. Felix Gradstein (2021). (Courtesy of Prof. F.M. Gradstein)

Biography

Born in 1941 in Eindhoven, the Netherlands, Felix Gradstein studied paleontology and stratigraphy at the University of Utrecht under the supervision of Professor CW Drooger. This early research resulting in his PhD thesis (Gradstein 1974) was concerned with a novel biometrical approach in micropaleontology. After working 2 years for an oil company in Calgary, Canada, he joined the Geological Survey of Canada in its eastern division at the Bedford Institute of Oceanography in Nova Scotia. He was instrumental in developing a novel quantitative approach to the analysis of stratigraphic

events (observed highest or lowest occurrences in hydrocarbon wells or natural sections) ranking and scaling them, initially for the Northwest Atlantic continental margin (Gradstein and Agterberg 1982). Since then, Ranking and Scaling (RASC) has remained a key method for quantitative biostratigraphy of fossil event data. In 1992 Felix moved to Norway where he currently has an office at the University of Oslo.

Gradstein's major contributions to geoscience included his work on the Geologic Time Scale that started in 1985/1986 when he helped construct the Decade of North America geologic time scale (Kent and Gradstein 1986). This was the first scale to use the Mesozoic marine magnetic anomaly patterns for stage scaling. Soon thereafter Felix took over from Professor WB Harland as editor-in-chief of the international Geologic Time Scale (GTS) project. His first GTS (Gradstein et al. 2004) was published by Cambridge University Press, but the 2012 and 2020 versions were published by Elsevier. GTS2020 had a team of 4 editors to standardize all radiogenic isotope ages, the mathematical interpolations, and the many Periods and specialist discipline chapters contributed by over 100 specialists. For the Cenozoic, GTS2020 is entirely based on Milankovic'-based astrocylicity. For nearly all of the Mesozoic and Paleozoic, cubic-spline fitting (age versus chronostratigraphy) was used for scaling and 95% confidence intervals were estimated for the stage boundary ages.

Currently, Felix is Professor Emeritus at Oslo University, Norway, and visiting Research Fellow, University of Portsmouth, UK. From 2000 to 2008, he was chair of the International Commission on Stratigraphy. Under his leadership, major progress was made with the formal definition of chronostratigraphic units from Precambrian through Quaternary. His major contributions to the geosciences have been widely recognized. For his fundamental work concerning the Geologic Time Scale, geochronology in general, quantitative stratigraphy and micropaleontology, the European Geosciences Union awarded him in 2010 the Jean Baptiste Lamarck Medal. He is Chair of the Geologic Time Scale Foundation and teaches courses in quantitative stratigraphy and the geologic time scale. After completion of GTS2020, he has free time again and studies the early evolution of planktonic foraminifera.

Synonyms

Crystal size analysis; Granulometry; Particle size analysis

Definition

Grains are three-dimensional objects of a size between that of dust particles and rock fragments. They can be loose, as sand or dust grains or fragments of broken stones, or may appear as embedded objects like crystals or pores in textures of stones. Typically, populations of grains are studied. Care is necessary when grains contain smaller objects, which also may be called “grains” in the same context.

This entry always uses the general term “grain,” which is specified where needed as “loose grain” or “embedded grain.” Size is a geometric characteristic of a grain. It is often a one-dimensional quantity like diameter, which may result from two- or three-dimensional measurement and some calculation, where grain shape plays an important role. There are many different methods of measurement and specialized statistics.

Overview

Dispersed materials are omnipresent both in nature and in the way in which humans use nature. In geosciences, grain size analysis is often used to characterize dispersed materials, which are powdery, granular, or lumpy material mixtures. This ranges from loose rock material such as soil or more general sediments to blasted or crushed hard rock in mining. However, grain size analysis is not limited to rock materials

but also applied for numerous other tasks like characterizing suspended sediments in water bodies or quantifying the texture of mineral material, which is often formed by a multitude of grains.

Standard references to grain size analysis are Allen (1990) and Bernhardt (1994). Both textbooks approach the topic in a relatively general way. If the size of embedded grains like crystals is in the focus, Higgins (2006) and Randolph and Larson (1988) are valuable references. Further, Rumpf and Scarlett (1990) gives a summary for natural materials, which are further processed, like crushed hard rock. The notation of the international standard ISO 9276-1 (2004) is used as far as possible in the following.

Grain Size

Grain size analysis is always bound to the *definition* of grain size, the size of the individual three-dimensional elements forming grain collectives. Unlike regular geometric objects like spheres or cubes, there is no single axiomatic parameter to describe the size of an irregularly shaped grain. In contrast, there is a multitude of size definitions, which mainly depend upon the type of grain and measurement. The measurable physical properties used to characterize the size x of a grain can be grouped as follows:

- (a) *Characteristic length parameters*: The grain size can be defined by geometric lengths, which are directly measured from the grain or from a sectioned or projected grain outline.
- (b) *Surface or projected area*: The grain size can be characterized by its surface, which can be measured with gas-adsorption methods. However, measuring the projection area is more common since it can be realized relatively simple with means of image processing.
- (c) *Volume or mass*: The volume of coarse grains can be measured by fluid displacement. A simpler method is weighting.
- (d) *Stationary sedimentation rate*: Assuming objects of the same density and similar shape, their sedimentation rate in a fluid is only affected by their sizes. Hence, this characteristic can be used to define grain size.
- (e) *Field disturbance effects*: The size of relatively small grains can often be determined by reliably measuring their interference effects with electric, electromagnetic, or fluid-dynamic fields.

Table 1 shows some common geometrical definitions of grain size. Often, a spherical reference grain is used to ease

understanding if originally higher-dimensional characteristics were measured. An example is the Stokes diameter d_{st} .

Grain Size Distributions

Usually populations of grains are considered, the sizes of which are variable. Size measurement leads to data lists, which are statistically analyzed.

The Cumulative Size Distribution Function $Q_r(x)$

The variability of grain sizes x is usually described by grain size distribution functions $Q_r(x)$ for $r = 0, 1, 2, 3$. These functions describe how many grains measured in the quantity type r (Table 2) are smaller than a given grain size x for $x_{\min} \leq x \leq x_{\max}$. Commonly, the mass distribution with $r = 3$ or the number distribution with $r = 0$ are used.

In particular

$$Q_0(x) = \frac{\text{number of grains} < x}{\text{total number of grains}} \quad \text{for } x_{\min} \leq x \leq x_{\max}, \quad (1)$$

$$Q_3(x) = \frac{\text{mass of grains} < x}{\text{mass of all grains}} \quad \text{for } x_{\min} \leq x \leq x_{\max}. \quad (2)$$

Frequently these distributions are given in histogram form according to the principle of measurement.

The cumulative size distribution $Q_r(x)$ is plotted against grain size x . In many cases it is practicable to use a logarithmic scale for $r = 3$ (Fig. 1).

The use of a plot with logarithmic x -scale is quasi-standard in some application fields, since size differences between 0.1 mm and 0.2 mm are frequently considered of the same importance as size difference between 1 mm and 2 mm.

The Probability Density Function $q_r(x)$ of Grain Size

Given that the cumulative distribution function $Q_r(x)$ is differentiable, there exists the probability density function $q_r(x)$, which is given by:

$$q_r(x) = \frac{dQ_r(x)}{dx} \quad \text{for } x_{\min} \leq x \leq x_{\max} \quad (6)$$

The density function can be estimated by means of kernel estimators; however, there are difficulties since the data are often given in histogram form. Analogously to the cumulative size distribution function, it can be useful to plot the frequency distribution in a log-normal plot.

Grain Size Analysis, Table 1 Definitions of grain sizes

Symbol	Name	Definition	
<i>Size definitions based on projections or sections</i>			
d_M	Martin's diameter	Length of the area bisector in measuring direction	
d_F	Feret's diameter	Distance between two parallel lines restricting the object perpendicular to the measuring direction	
d_C	Maximum chord	Maximum chord length in measuring direction	
d_p	Perimeter diameter	Diameter of a circle having the same circumference as the projected outline of the particle	
d_A	Projected area diameter	Diameter of a circle having the same area as the projected outline of the particle	
<i>Size definitions based on spatial characteristics</i>			
a	Length	Length of the bounding box	
b	Width	Width of the bounding box	
c	Height	Height of the bounding box	
d_v	Volume diameter	Diameter of a sphere having the same volume as the particle	
d_s	Surface diameter	Diameter of a sphere having the same surface as the particle	
d_{St}	Stokes diameter	Diameter of a sphere having the same density and in the laminar flow region the same free-falling velocity as the particle in a fluid of the same density and viscosity	

Figure 2 shows a typical histogram and the corresponding constructed probability density functions in linear and logarithmic scale. The intervals of both histogram bins are in geometric progression; hence, the histogram bars are of increasing and equal width, respectively.

Models for Distribution Functions

Besides normal, log-normal, and gamma distributions, several more specific distribution functions have proven useful in practice. The most important are:

- Rosin-Rammler-Sperling-Bennett (RRSB) distribution, also called Weibull distribution, with scale parameter x' and shape parameter n ,

$$Q_3(x) = 1 - \exp\left(-\left(\frac{x}{x'}\right)^n\right) \quad \text{for } x \geq 0, \quad (12)$$

where x' satisfies $Q_3(x') = 1 - \frac{1}{e}$ and typically $0.5 \leq n \leq 2$.

- Gates-Gaudin-Schuhmann (GGS) distribution with scale parameter $x_{\max}$ and shape parameter n :

$$Q_3(x) = \left(\frac{x}{x_{\max}}\right)^n \quad \text{for } 0 \leq x \leq x_{\max} \text{ and } n > 0. \quad (14)$$

- Gaudin-Melloy (GM) distribution with scale parameter $x_{\max}$ and shape parameter n :

$$Q_3(x) = 1 - \left(1 - \frac{x}{x_{\max}}\right)^n \quad \text{for } 0 \leq x \leq x_{\max} \text{ and } n > 0. \quad (15)$$

These distributions are frequently used, but experience shows that often the fit at the tails is of low quality. To overcome such shortcomings, tailor-made model adjustments are used, e.g., the three parameter RRSB distribution function, where an additional term $x_{\min}$ is used.

Analysis Methods

Grain sizes are measured in different approaches and methods, depending on the fineness and accessibility of the grains. The following are brief outlines of such methods; for details we refer to Allen (1990), Bernhardt (1994), and Higgins (2006).

Sieve Analysis

Sieve analysis is a popular measurement approach for loose grains in the range of 5–125 mm. During sieving the material is separated into fractions, the masses of which are determined and compiled as histograms. The analysis can be done consecutively with single sieves or in parallel with a set of sieves by hand or by machine with different setups, mostly depending on the material properties. The loose grains

Grain Size Analysis,

Fig. 2 Histograms and corresponding density functions obtained by kernel estimators in linear and logarithmic scale

are transported through the mesh openings by inertia forces, by gravity and/or flow forces, or by hand if very large grains are sieved.

Imaging Particle Analysis

This complex of analysis methods is based on images taken with cameras, microscopes, X-ray detectors, etc. The grains can be loose like fractured rock as well as embedded grains like crystals in a mineral microstructure. While microstructures are analyzed in a static or quasi static setups, for example, under a microscope or in a tomograph, images of loose grains can also be taken in a dynamic situation, like sand in a flow (Fig. 3).

Based on the kind of images it can further be distinguished between approaches for the analysis of projections, sections, or spatial images like those resulting from tomography. In theory, the size resolution of imaging particle analysis is only limited by the resolution of the imaging method.

For deriving grain sizes of projections or sections of original three-dimensional objects, size parameters can be calculated directly from measured parameters like area or perimeter of the outlines. However, those are fraught with uncertainties, since the spatial character of the measured objects is only partly taken into account. To overcome this, stereological methods for either sections or projections can be applied. In this context, stereology offers a comprehensive toolbox to calculate spatial characteristics based on specific assumptions on the grain shape and orientation. In contrast, it is possible to measure spatial characteristics directly on spatial images by means of tomography without further assumptions, which is a great benefit. However, tomography is difficult when objects with similar physical properties, like crystals of the same material, are touching each other. (Since tomography methods measure the interactions between penetrating waves and the matter of the objects and X-ray absorption and refraction are

isotropic for all materials, it is hardly possible to distinguish adjoining objects if they have similar properties (Baker et al. 2012).) Furthermore, tomography needs rather complex measurement instruments and produces huge datasets, and the evaluation of tomography data needs special statistical methods (Ohser and Schladitz 2006).

As an example, for the application of stereological methods, grain measurement for the quartz grains in Fig. 4 is discussed. For the analysis of such planar sections there exist some solutions in the mineral-related literature. One, see Higgins (2000, 2006), assumes that the grains are parallelepipeds or ellipsoids, whereas another, see Popov et al. (2014), assumes ellipsoids. In the planar section the areas of the section profiles are measured. By means of approximate stereological methods then grain shape is characterized according to the assumed geometry and some linear size characteristic, which is the diameter of volume-equivalent sphere for Popov and maximum length or major axis of equivalent ellipsoid in the Higgins approach. The Popov method is parametric and uses the log-normal distribution. Figure 4 shows the solutions for both approaches for the quartz grains.

Light Scattering Methods

If a loose grain is irradiated with light, several interactions like light scattering occur. Since the intensity of the scattered light is a function of grain size, this principle can be used for grain size measurement.

In this context, there exist two main measuring principles. The first is direct measurement of scattered light, which allows measurement of loose grains in the narrow size range between 0.1 μm and 50 μm . The second is measurement of extinction caused by a loose grain in a light beam. This method of measurement has a lower limit of approximately 1 μm but is theoretically capable of measuring grains up to the

Grain Size Analysis,

Fig. 3 Imaging particle analysis of a static microstructure and of moving loose grains. For grain size analysis, either direct measures of the planar projections can be used or spatial length measures are calculated with stereological tools

Grain Size Analysis,**Fig. 4** Thin section

(35 mm × 31 mm) of a granite and corresponding empirical log-normal distributions for grain size of quartz

size of centimeters. For both measuring principles, the grains have to be dispersed into a gas or a fluid.

For measuring grain size with light scattering, a variety of solutions with different requirements and specifications are available. To measure the size of solid grains, solutions with absorbance measurement are commonly used. There, the material is dispersed in a liquid or a gas and transported through a measurement cell where the grains are measured automatically.

Sedimentation Analysis

Since the settling behavior of loose grains in a fluid largely depends on their size, the sedimentation principle provides a basis for grain size analysis. Both, gravitation and centrifugal force can be used. Generally, two main approaches are distinguished. For the incremental method, the rate of change of density or concentration is used, while the cumulative approach uses the settling rate of loose grains. While measures based on the first method are fast, an advantage of cumulative measurement is that it works also with small amounts of material, which reduces the error due to interactions between the settling grains.

Sedimentation analysis allows various measurement setups of different complexity (Allen 1990; Bernhardt 1994). It is mainly used for the analysis of fine grains in the lower micron range. If sedimentation in a laminar flow field is used, the Stokes diameter d_{St} serves as reference size:

$$d_{St} = \sqrt{\frac{18\eta}{(\rho_g - \rho_f) \cdot g}} \cdot w_s, \quad (11)$$

where η – dynamic viscosity of the fluid, ρ_g – grain density, ρ_f – fluid density, g – acceleration due to gravity or centrifugal force, w_s – settling velocity of the loose grain. This implies that the grain Reynolds number calculated for the Stokes diameter is below the value of 0.25.

Particle imaging and light scattering methods benefit from advances in computer technology and optoelectronics, whereas sedimentation analysis has lost some of its importance. However, it is still considered one of the most important methods of grain size analysis.

Summary

The size of grains is measured by various methods, which are adapted to the nature of the material. There is a tendency to use more and more computer techniques. Grain size is defined in different ways, in dependence of the material and the method of measurement. The data obtained are analyzed statistically, using various special distribution functions. The statistics is difficult for the tails of distributions, for very small or very large grains. For embedded grains stereological methods are used.

Graph Mathematical Morphology

Rahisha Thottolil and Uttam Kumar

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Mathematical morphology provides a set of filtering and segmenting tools for image analysis. Here, an image space is considered as a graph where the connectivity of the pixels/grids is taken into account. A simple graph is a collection of vertices and edges, and it is denoted as $G = (X^*, X^\times)$, where X^* is a non-empty set of vertices and $X^\times$ (representing adjacency relation among the vertices) is composed of pairs of distinct vertices from X^* called edges. In other words, each element of X^* is called a vertex or a node point of a graph G , and each element of $X^\times$ is called an edge of a graph G . A simple graph is an undirected graph where each edge connects two different vertices and no two edges connect the same pair of vertices. Graph mathematical morphology (GMM) is a systematic theory and has been developed on these graph spaces (G). GMM extracts structural information from simple and small pre-defined structuring graphs by constructing morphological operators such as openings and closings. However, morphological transformations by GMM are restricted by their graph structure like the subsets of vertices, the subsets of edges, and the sub-graphs of graphs.

Introduction

The term morphology is widely used in the field of biology that deals with the shape and structure of plants and animals. However, in this chapter, we outline the important concept of mathematical morphology (MM) in the context of graphs that

has wide applications in digital image processing. MM was introduced in mid-1960s by two researchers Georges Matheron and Jean Serra (Youkana 2017) for investigating the structures present in crystals and alloys. The theoretical basis of a morphological operator was derived from set theory and integral geometry (Heijmans and Ronse 1990). Initially, MM was applied on binary, gray-scale and color images. Luc Vincent (1988) extended the application of MM from image space to graph space. Later, MM operators were applied on multivalued data such as in remote sensing and geoscience applications, medical image analysis, and astronomy to extract spatial features. This chapter aims to present a brief introduction of classical morphology operators on two-dimensional binary and gray-scale images and discuss graph-based mathematical morphology (GMM). In the following section, important terminologies used in morphological methods are defined.

A 2D binary image is assumed to be represented in the form of a point set (vector in 2D space), where each pixel is an image point with value 0 or 1, whereas in the case of a gray-scale image, the value of an image point is an ordered set of gray levels (e.g., 8-bit image value ranges from 0 to 255). Figure 1 (a) and (b) shows examples of a discrete binary and gray-scale images, where each image pixel (point) is represented as a grid.

In practice, the points belong to an area of interest (building footprint illustrated in white pixels) in Fig. 1a and are represented as a point set X . It means, $X = \{(x_0, y_0), (x_0, y_1), \dots, (x_i, y_i)\}$, and all the points (x_i, y_i) belong to the location where the area of interest/object is present, which is a simple morphological description of an image. Similarly, the background pixels (black) can also be represented in the form of a point set, which is the complement of $X(X^c)$. In case of gray-scale, it is a multidimensional (n) image and is represented as a set of points, $X \subset E^n$, where E^n is n -dimensional Euclidian space. However, Fig. 1b illustrates the concept of E^n on a 2D gray-scale image, where each grid denotes a single pixel, then $(n - 1)$ coordinates represent the spatial domain, and n^{th} coordinate represents the value of the function.

Morphological operation on an image involves a relation of the point set X with another small structural point set (B). Generally, B is a small subset of a binary image (called structuring elements: $SE(B)$ defining the neighborhood of the points) that uses probes with well-defined shape and size to extract specific information (Heumans et al. 1992). Here, one of the pixels represent an origin (usually center pixel), and its size is based on the dimension of matrix while shape depends on the position of values ones or zeroes (Youkana 2017). It is to be noted that the selection of SE is done by considering the image geometry and prior knowledge of spatial properties of an object. Usually, flat SE are used in

Graph Mathematical Morphology, Fig. 1 Example of (a) a binary image and (b) a gray-scale image

case of 2D image analysis, and non-flat SE are used for higher dimensional images. Once the image and $SE(B)$ are represented in the form of sets, then MM operators on images are basic set operations (usually nonlinear) on the point sets. In practice, $SE(B)$ moves systematically over the input image(X), and the performance of operation depends on the type of SE s and translation operations applied. To learn more about the theoretical aspects of classical morphology, we need to define a complete lattice notion which is the fundamental source of MM operations.

Fundamental Operators: Dilation and Erosion

The fundamental morphological operators are dilation (δ) and erosion (ε) (Heijmans and Ronse 1990). The dilation operation is implemented in terms of union (the Minkowski addition) of two sets. We denote the dilation of a set X over a $SE(B)$ by $\delta(X)$ as shown in Eq. (1) in 2D space ($\mathbb{Z}$).

$$\begin{aligned}\delta(X) &= X \oplus B = \{p \in \mathbb{Z}^2 / p = x + b, x \in X, b \in B\} \\ &= \cup_{b \in B} X_b\end{aligned}\quad (1)$$

The erosion operation of a set X by $SE(B)$ - $\varepsilon(X)$ is defined in terms of intersection (the Minkowski subtraction) operation of two sets as given by Eq. (2), where $X-b$ denotes the translation of X by $-b$.

$$\begin{aligned}\varepsilon(X) &= X \ominus B = \{p \in \mathbb{Z}^2 / (p + b) \in X, b \in B\} \\ &= \cap_{b \in B} X_{-b}\end{aligned}\quad (2)$$

In general, after applying dilation operation on an image, the regions of an object area expand and noisy pixels are removed from the object region. In contrast, erosion is an inverse operation of dilation where the boundary of an object gets eroded. Interestingly, both the operators are dual by complementation and can be applied at various levels such as during pre-processing, analysis, and post-processing of an

image. Dilation of an image is always commutative with $SE(B)$ and always associative with different SE . To compensate for the distraction of object shape in image processing, we use the combination of these basic MM tools with the same $SE(B)$. The implementation of dilation and erosion on gray-scale image (F) consists of finding the maximum and minimum of original image (F) respectively, as given by Eqs. (3) and (4).

$$\delta_B(F) = \max_{b \in B} [F(x + b)] \quad (3)$$

$$\varepsilon_B(F) = \min_{b \in B^v} [F(x + b)] \quad (4)$$

In case of dilation, the algorithm finds the maximum value of the original image within the scope of the SE , whereas erosion consists of minimum value of F . Erosion and dilation operations are considered as adjunction pairs of basic morphological operators (δ, ε). Most of the morphological algorithms are derived from these two basic elementary operations.

Morphological Filtering: Opening and Closing

Two main filtering operators derived from the composition of dilation and erosion are opening ($X \circ B$) and closing ($X \bullet B$). Thus, the opening of X by B is an anti-extensive ($\gamma(x) \leq x$) filtering function. Opening and closing filters on a binary image are expressed as follows:

$$\gamma_B(X) = X \circ B = (X \ominus B) \oplus B \quad (5)$$

$$\varphi_B(X) = X \bullet B = (X \oplus B) \ominus B \quad (6)$$

The opening operation on an image (X) by $SE(B)$ is defined as the erosion of X by B followed by a dilation of the results by the same SE . Likewise, the closing operation on an image X is the dilation of X by B followed by an erosion of the result by

B , which is extensive ($x \leq \varphi(x)$). Both the filters are complementary to each other. Opening operations are useful for smoothening the contour of the objects present in an image and to remove the long narrow gaps. Further, closing fuses narrow gaps and removes small patches by filling the contour breaks. While applying a closing filter, we can remove all the internal noise present in the region, and by using an opening filter, the external noise is removed from the background region of an image.

Composing closing and opening operations with increasing size of SE is called an alternate sequential filter (ASF). These MM algorithms have practical use cases in image processing such as extracting boundary of an object, region filling, extracting connected components, retrieving convex hull information from high-level images, thinning and thickening operations, and enhancing the object structure by skeletonization. During pre-processing, applications such as filtering of salt and pepper noise, shape simplification (i.e., complex structured object broken into a number of simple structures), extracting image components such as segmentation of an image by using object shape, quantification of geometric features (area, perimeter and axis length) of an object present in an image, and object masking, etc. are possible. Efficient filters can be obtained for image processing by various compositions and iterations of basic morphological operators.

Basic Concept of Graphs

In this section, we describe how to extend the classical morphological operation from image to graph spaces. Generally, the image space is considered as a graph whose vertex set is generated from pixels, and the edges represent the local pixel adjacency relation or Euclidian distance between the pixels.

In a 4-pixel adjacency graph, the weight of an edge is the distance between the neighboring pixels, and to model color images, the edge weights represent the similarity or dissimilarity between the neighboring pixels (Danda et al. 2021). Edge weight is computed by taking the absolute Euclidian

difference between the adjacent pixels and it is called discrete gradient. These edge-weighted graph models are useful for image segmentation and filtering. The objects that appear in an image have structural information, therefore, MM operators can be applied on more complex data structures like graphs and hypergraphs. For example, in the field of transportation, road networks are represented as a planar graph. In such cases, the intersection of roads and endpoints is represented as vertices and road segments correspond to edges. The distance between the vertices is some kind of a measure and the graph representation of the road network describes its spatial pattern. The basic concept of a graph in the form of a road network is shown in Fig. 2 (a) and (b) where vertices are represented by red dots and the edges by yellow line segments.

In GMM operators, SE are extracted from the graphs using predefined probes (structuring graphs) (Heijmans et al. 1992). Similar to the SE , structuring graphs are also small as compared to the input graph. Cousty (2018) proposed a large collection of morphological operators acting on graphs such as dilation, erosion, opening and closing, granulometries, and alternate sequential filters. Here, the input operands and the result of the operators were both considered as graphs (Cousty et al. 2013).

MM Operators on Graphs: Dilation and Erosion

Here, operands are considered as a graph and the basic morphological operators are defined. Complex structures and relations with neighboring structures present in an image are represented by simple (unweighted) graphs.

A dilation operator on a graph with the set of vertices X^* is illustrated in Fig. 3a, b (Cousty 2018; Youkana 2017). The dilation operator from the set of vertices expands to all the neighboring vertices which are connected through edges. Dilation operator on a graph with subgraphs as shown in Fig. 3 (c) and (d) shows that dilation enrich by expanding the set of elements with the adjacent and connected vertices and edges.

Graph Mathematical Morphology, Fig. 2 (a)

Undirected road network represented as a simple graph, (b) road network overlaid on Google Earth image

Graph Mathematical Morphology, Fig. 3 Illustration of dilation operation on set of vertices (a–b) and subgraphs (c–d) (Cousty 2018)

The graph space $G = (X^*, X^\times)$, the set of x^* is the subset of X^* , $x^\times$ is the subset of $X^\times$, and $g = (g^*, g^\times)$ is the subgraph of G from the complete lattice. Four elementary building blocks on graphs are used to derive a set of edges from a set of vertices and a set of vertices from a set of edges (Cousty 2018). The dilation and erosion operators of vertices (δ^* & ε^*) map from $g^\times$ to g^* , and the operators of edges ($\delta^\times$ & $\varepsilon^\times$) map from g^* to $g^\times$ as illustrated in Fig. 3.

$$\delta^*(X^\times) = \{x \in G^* \mid \exists \{x, y\} \in X^\times\}, \text{ for any } X^\times \subseteq G^\times \quad (7)$$

$$\varepsilon^*(X^\times) = \{x \in G^* \mid \forall \{x, y\} \in G^\times, \{x, y\} \in X^\times\}, \text{ for any } X^\times \subseteq G^\times$$

(8)

In Eq. 7, the dilation operator maps to any set of edges $X^\times$ denoted as $\delta^*(X^\times)$, which results in all the set of vertices that belong to an edge $X^\times$. The erosion operator $\varepsilon^*(X^\times)$ maps to any

set of edges $X^\times$ (Eq. 8) that results from the set of vertices that are completely covered by edges $X^\times$. Resultant graphs are shown in Fig. 4a, c.

The erosion operator $\varepsilon^\times$ maps to any set of vertices X^* , the set of all edges whose two extremities are in X^* (Eq. 9). The dilation operator $\delta^\times$ maps to any set of vertices X^* , the set of all edges that have at least one extremity in X^* (Eq. 10). Resultant graphs are shown in Fig. 5a, c.

$$\varepsilon^\times(X^*) = \{\{x, y\} \in G^\times \mid x \in X^* \text{ and } y \in X^*\}, \text{ for any } X^* \subseteq G^* \quad (9)$$

$$\delta^\times(X^*) = \{\{x, y\} \in G^\times \mid x \in X^* \text{ or } y \in X^*\}, \text{ for any } X^* \subseteq G^* \quad (10)$$

Graph Mathematical Morphology, Fig. 4 Operators acting on the lattice from g^* to g^* (Cousty 2018)

Graph Mathematical Morphology, Fig. 5 Operators acting on the lattice from g^* to g^* (Cousty 2018)

The dilation operator commutes with union set operation, and the intersection operation is erosion. MM operators on binary unweighted graphs commute with set operations as follows:

$$\delta^*(X^\times \cup Y^\times) = \delta^*(X^\times) \cup \delta^*(Y^\times), \text{ for any } X^\times, Y^\times \subseteq G^\times \quad (11)$$

$$\varepsilon^*(X^\times \cap Y^\times) = \varepsilon^*(X^\times) \cap \varepsilon^*(Y^\times), \text{ for any } X^\times, Y^\times \subseteq G^\times \quad (12)$$

$$\delta^\times(X^\bullet \cup Y^\bullet) = \delta^\times(X^\bullet) \cup \delta^\times(Y^\bullet), \text{ for any } X^\bullet, Y^\bullet \subseteq G^\bullet \quad (13)$$

$$\varepsilon^\times(X^\bullet \cap Y^\bullet) = \varepsilon^\times(X^\bullet) \cap \varepsilon^\times(Y^\bullet), \text{ for any } X^\bullet, Y^\bullet \subseteq G^\bullet \quad (14)$$

where $\delta^\times$ and δ^* are called vertex-edge dilation and edge-vertex dilation. Similarly, $\varepsilon^\times$ and ε^* are called vertex-edge erosion and edge-vertex erosion, respectively. The elementary vertex dilation ($\delta(X^\bullet) = \delta = \delta^* \circ \delta^\times$) and edge dilation ($\delta(X^\times) = \delta = \delta^\times \circ \delta^*$) by composition of the vertex-edge dilation and edge-vertex dilation. Likewise, vertex erosion ($\varepsilon(X^\bullet) = \varepsilon = \varepsilon^* \circ \varepsilon^\times$) and edge erosion ($\varepsilon(X^\times) = \varepsilon = \varepsilon^\times \circ \varepsilon^*$) are obtained by the composition of the vertex-edge erosion and edge-vertex erosion. In case of morphological analysis on

gray-scale images, intensity value is also considered; therefore, MM operators are proposed on weighted graphs. The major applications of gray-scale morphology are contrast enhancement, texture extraction, edges detection, and thresholding. Definitions involved in gray-scale graph morphological operations are shown below:

Let $F^\bullet \in I(X^\bullet)$ and $F^\times \in I(X^\times)$; then MM operators are

$$\delta^*(F^\times)(x) = \max\{F^\times\{x, y\} \mid \{x, y\} \in X^\times\}, \forall x \in X^\bullet \quad (15)$$

$$\varepsilon^\times(F^\bullet)\{x, y\} = \min\{F^\bullet(x), F^\bullet(y)\}, \forall \{x, y\} \in X^\times \quad (16)$$

$$\varepsilon^*(F^\times)(x) = \{F^\times\{x, y\} \mid \{x, y\} \in X^\times\} \forall x \in X^\bullet \quad (17)$$

$$\delta^\times(F^\bullet)\{x, y\} = \max\{F^\bullet(x), F^\bullet(y)\}, \forall \{x, y\} \in X^\times \quad (18)$$

Grayscale image dilation involves assigning the maximum value over the neighborhood of the SE . In contrast, erosion involves assigning minimum value over the neighborhood of the SE (Cousty et al. 2013).

Morphological Filters on Graphs

Graph-based morphological filters such as opening and closing were obtained from the composition and iteration of dilation and erosion either by applying on set of vertices and

set of edges or subgraphs of graph G . The number of iteration operations (also called parameter size denoted as ' λ ') is important in opening and closing filters. The value of λ depends on the size of the features to be preserved or removed (Youkana 2017). Filtering operators depend on the order of basic MM operators, and their complexity corresponds to the value of λ and the size of the graphs.

We denote opening and closing on vertices by γ , ($\gamma = \delta \circ \varepsilon$) and ϕ , ($\phi = \varepsilon \circ \delta$), respectively. Similarly, opening and closing on edges are denoted by Γ , ($\Gamma = \Delta \circ E$) and Φ , ($\Phi = E \circ \Delta$), respectively. Combination of these operators gives opening ($[\gamma, \Gamma]$) (Eq. 19) and closing ($[\phi, \Phi]$) (Eq. 20) on a graph G .

$$[\gamma, \Gamma] = [\gamma(X^\bullet), \Gamma(X^\times)] \quad (19)$$

$$[\phi, \Phi] = [\phi(X^\bullet), \Phi(X^\times)] \quad (20)$$

We can deduce the operators on the subgraph of graph called half-opening and half-closing (Najman and Cousty 2014). The series of these morphological filters are called granulometries. Furthermore, an alternate sequence of filters can be derived from intermixing of opening and closing with the increasing size of structuring graph. It has been found that GMM operators are more efficient than image-based operators (Youkana 2017). However, a major drawback of graph-based image analysis is the images with a large number of pixels that have very high asymptotic complexity (Danda et al. 2021).

Application of MM and GMM

Graph-based MM operations have been used in applications involving quantitative description of spatial relationship between objects in images. Heijmans and Vincent (1992) studied the heterogeneous media at a macroscopic level based on the information on their microstructure by GMM. Furthermore, GMM filtering on preprocessing of medical images with higher accuracy among existing operations were demonstrated by Cousty (2018). The usage of GMM based ASF has proved to render minimum mean square error for noise removal (Cousty et al. 2013; Youkana 2017). GMM models have also been applied successfully for various image segmentations and filtering applications including astronomical images (Danda et al. 2021) and for segmentation of 3D images from multimodal acquisition devices (Grossiord et al. 2019). However, application of GMM in geospatial data analysis is a field of ongoing research. Hence, there is a tremendous scope of applied GMM in remote sensing data analysis.

Summary

The concept of morphological techniques discussed in this chapter constitutes a significant tool in the image-based geoscience data analysis. The main purpose of mathematical morphology operation is the quantitative description of spatial features of the objects, specifically, extracting meaningful information from noisy images. Dilation and erosion are the fundamental morphological operators, and all other morphological algorithms are derived from these primitive functions. In the first part, MM operators on binary and gray-scale image space were discussed. In the second part, we focused on the framework of MM operators on graph space. Finally, we summarized a few studies in the field of GMM.

Definition

Gray-scale morphology encompasses all operators from mathematical morphology (MM) on gray-scale images. MM operators are defined on complete lattices. Gray-scale images constitute a specific lattice. This allows the definition of the MM operators to be simplified. In this entry we shall give an overview of different gray-scale morphological operators. Detailed explanation of these operators can be found in their respective chapters and the books Najman and Talbot (2013), Soille (2004), and Dougherty and Lotufo (2003).

A gray-scale image is represented as a function, $f: E \rightarrow \{0, 1, 2, \dots, 255\}$ where E is either $\mathbb{R}^2$ or $\mathbb{Z}^2$. If the domain is $\mathbb{Z}^2$ it is referred to as a discrete image.

Two Kinds of Structuring Element

Recall that the structuring element in the gray-scale case is another gray-scale image with restricted domain. The structuring element is also referred to as structuring function in few places. There are two kinds of structuring elements based on the values the gray-scale image can take – *Flat* structuring element takes only a value 0 while *Non-flat* structuring element can take any positive values.

Basic MM Operators on Binary Images

The following are the basic operators from mathematical morphology adapted to gray-scale images.

1. *Dilation*: Given a gray-scale image f and a structuring element g , the dilation is defined as

$$\delta_g(f) = (f \oplus g)(x) = \sup_{y \in E} \{f(y) + g(x - y)\} \quad (1)$$

2. *Erosion*: Given a gray-scale image f and a structuring element g the erosion is defined as

$$\varepsilon_g(f) = (f \ominus g)(x) = \inf_{y \in E} \{f(y) - g(x - y)\} \quad (2)$$

3. *Opening*: Given a gray-scale image f and a structuring element g the opening is defined as

$$\gamma_g(X) = \delta_g \circ \varepsilon_g(f) \quad (3)$$

4. *Closing*: Given a gray-scale image f and a structuring element g the closing is defined as

$$\phi_g(X) = \varepsilon_g \circ \delta_g(X) \quad (4)$$

Filtering on Gray-Scale Images

A morphological filter on a gray-scale image is any operator that is increasing and idempotent and can be obtained using the dilation/erosion operators above. The opening/closing operators above form the basic filters. Several families of filters can be constructed from these operators.

1. *Granulometries*: The idea of a granulometry is similar to filtering out particle based on their sizes. Using the opening operator we can define it as.

$$\text{Granulometry} = \gamma_{ng} \circ \gamma_{(n-1)g} \circ \dots \circ \gamma_{2g} \circ \gamma_g \quad (5)$$

Not all structuring elements g are allowed. Usually flat structuring elements with the domain constrained to be a disk or line-segment is considered.

2. *Alternating Sequential Filters*: For gray-scale images where noise is spread across different scales and contains both bright and dark distortions, using alternate sequences of opening and closing would help.

$$\text{ASF} = \phi_{ng} \circ \gamma_{ng} \circ \phi_{(n-1)g} \circ \gamma_{(n-1)g} \circ \dots \circ \phi_g \circ \gamma_g \quad (6)$$

One can also start with closing instead of opening as in the above definition.

On the other hand one can define an *algebraic filter*, which is any operator that is increasing and idempotent. Examples of algebraic filters include – Area Opening, Attribute Openings, Annular Opening, Convex Hull Closing, etc.

Other Operators on Gray-Scale Images

A host of operators can be defined on binary images. A few are stated below.

1. *Geodesic Dilation/Erosion*: The geodesic operations force the output to belong to a mask f' . A single step of geodesic dilation is defined as

$$\text{Geo} - \text{Dilate}^{(1)}(f) = \delta_g(f) \wedge f' \quad (7)$$

One can suitably define geodesic erosion as well. These operators can be repeated to obtain higher order dilations or erosions.

2. *Thinning/Thickening*: One can define the notions of thinning/thickening by considering two structuring elements, respectively, for foreground/background pixels. See Soille (2004) for details.
3. *Skeletonization* involves reducing the binary image to a one-dimensional caricature to extract the most discerning features in the image.
4. *Segmentation* of gray-scale images involves partitioning the domain such that pixels within a component (of partition) belong to the same object. Several approaches to achieve this are proposed and the most commonly used one is that of *Watershed Transform*.

Summary

In this entry, elementary MM operators on gray-scale images, namely, gray-scale dilation, gray-scale erosion, gray-scale opening, and gray-scale closing are defined. Some of the popularly used operators that use these four elementary operations are then briefly described. These are granulometries, alternating sequential filters, geodesic dilation/ erosion, thinning/thickening, skeletonization, and watershed transform.

Griffiths, John Cedric

Donald A. Singer

U.S. Geological Survey, Cupertino, CA, USA

Fig. 1 John Cedric Griffiths

Biography

Professor John C. Griffiths was one of the founders of the International Association for Mathematical Geology. His impact on geology and other wide-ranging fields began in Llanelli, County Dyfed, Wales, in 1912. Griffiths earned a B.Sc. (1933), and Ph.D. (1937) degrees in petrology from the University of Wales, a Diploma of the Imperial College in petrology from the Royal College of Science, London, and Ph.D. degree in petrology from the University of London in 1940.

His recognition of the importance of practical experiences in teaching how to solve problems came partially from his 7 years (1940–1947) working for Trinidad Leaseholds Ltd. in the British West Indies. He directed more than 50 students during his following 40 years teaching in the Department of Mineralogy and Petrology of the Pennsylvania State

Donald A. Singer has retired.

University. Griffiths was recognized as a leader in applying statistics to the analysis of sediments. Between 1948 and 1962 he published many papers on improving analysis of sediments. This work culminated in his 1967 book (Griffiths 1967), *Scientific Method in Analysis of Sediments*. From this book one can see his increasing interest in modern scientific methods for problem solving such as decision theory, operations research, systems analysis, and search theory.

In 1970 with Ondrick (Griffiths and Ondrick 1970), he showed that randomly (uniformly distributed) points on a square surface could be fit with a Poisson distribution when sampled. If part of the square containing the same points was masked, only a negative binomial distribution could be fit to the points demonstrating a clustering of points. The points had not changed, only the ability to see some of them. This is not different from our perception of the clustering of mineral deposits – deposits known are mostly based on exposed rocks and exclude areas masked by younger cover. Insights like this led to his controversial proposal to grid-drill the United States to obtain unbiased data for national planning.

His teaching ability was so remarkable that the International Association for Mathematical Geosciences gives an annual award in his name for outstanding teaching in the application of mathematics to the geosciences. Students who expected to learn everything Griffiths knew soon recognized that this was impossible because he was continuing to learn and share new aspects of science every day. His students

learned applied statistics of spot, stratified and channel sampling schemes with pebble measurements in a partially layered gravel pit and in measures of size and shape of quartz grains and point counting of minerals in thin sections.

But each student was also exposed to a different set of classes throughout the university education. Classes varied for each student and ranged from industrial engineering, computer science, mineral economics, agronomy, chemistry, mathematical statistics, geology, to psychology. From these classes, students learned the commonality of problems with major differences being each discipline's language barrier. His teaching methods were unusual and by no means obvious to others. His students were taught how to define and solve scientific problems. The teaching award in his name by the International Association for Mathematical Geoscience was certainly appropriate.

Harbaugh, John W.

Johannes Wendebourg
TotalEnergies Exploration, Paris, France

Fig. 1 John W. Harbaugh, Courtesy of family Harbaugh's private collection

Biography

John W. Harbaugh (born August 6, 1926, died July 28, 2019) was a professor of mathematical geology at Stanford University where he taught quantitative methods for 44 years from 1955–1999. He received his undergraduate degree in geology from the University of Kansas in 1949 and his PhD from the University of Wisconsin in 1955. His main contributions to the field of mathematical geology are in the area of geological computer modeling where he pioneered modern simulation techniques, and in resource estimation methods. In 1968, he cofounded the International Association of Mathematical Geology (IAMG), from which he received the Krumbein award in 1985.

As a field geologist, Harbaugh worked mainly on carbonate rocks but quickly became interested in computer applications. His earliest work was on trend surfaces but quickly he moved to computer simulation. In 1970, he published together with Graeme Bonham-Carter the seminal book on *Computer Simulation in Geology* which treats a wide variety of subjects from stratigraphic modeling to geomorphology, including numerical methods (Harbaugh and Bonham-Carter 1970). This visionary book came into fruition some 15+ years later in the form of Stanford's Geomath program that he founded and ran from the early 1980s until 1999 and that was dedicated to the computer simulation of geological processes. The software called SEDSIM that he and his coworkers developed pioneered modern geological forward modeling techniques using novel Lagrangian numerical methods (Tetzlaff and Harbaugh 1989). Several monographs resulted from this work, including simulation of processes of sediment transport and deposition, and fluid flow in sedimentary rocks.

In the area of resource estimation, Harbaugh applied various statistical methods (Harbaugh et al. 1977) and worked closely together with John C Davis which culminated in a 500 + page monograph on risk analysis in oil and gas exploration (Harbaugh et al. 1995). Harbaugh also was interested in Markov processes applied to geology, as they are not purely random, and applied them to spatial representations of geology (Lin and Harbaugh 1984).

Harff, Jan

Martin Meschede

Institute of Geography and Geology, University of
Greifswald, Greifswald, Germany

Fig. 1 Jan Harff, 2002, on board with Professor Albrecht Penck (Photo: Foto Manthey)

Biography

Jan Harff was born in Güstrow in Mecklenburg (East Germany). After his Abitur in 1961 his first attempt to begin a study of architecture at the Technical University of Berlin failed caused by the Berlin wall construction. After some years in the building sector, he finally began his study of geology at the Humboldt University in East Berlin in 1964. The centrally controlled GDR university reform of 1968 forced him to continue his studies at the University of Greifswald in the northeasternmost part of Germany, where he finished his diploma in 1963. After this, he wanted to specialize in marine geology trying to get a position as a doctoral student at the Institute of Marine Studies in Warnemünde. On political reasons, however, he was not allowed to participate in the offshore research project, because he did not get the admission of the former socialistic regime of the GDR to pass the maritime boundary (Fig. 1).

Mainly caused by this denial, Jan Harff started his career as a mathematical geologist, first with a PhD thesis on classification methods on geophysical borehole data. After a short time at the district office of geology in Rostock, he switched to the Central Institute of Earth Physics (ZIPE, now German Research Centre for Geosciences, GFZ), where he was responsible to set up a department of mathematical geology,

a branch of geosciences which developed mainly in the 1970s. The main target of his investigations was to optimize the exploration methods of oil and gas using a theoretical basin model of the North German-Polish basin.

In 1991, after the German reunification, Jan Harff was offered the position as head of the project group mathematical geology at the newly formed GFZ (which substituted the ZIPE). However, after only 3 months at the GFZ, he got the chance of his life to become the head of the section marine geology at the Leibniz Institute of Baltic Research (IOW) in Warnemünde. With this job, his dream of marine geology came true and he could finally do what he wanted to do in the beginning of his career.

As member of the Institute of Baltic Research, Jan Harff was able to sail on various cruises, mainly using the IOW research vessel Professor Albrecht Penck in the Baltic Sea. Moreover, participations and expedition leaderships on international cruises with different German and Russian research vessels were a major part of his research activities. He concentrated on coastal regions and modeled, for instance, changes in the coastlines of the Baltic Sea according to the post-glacial uplift of Scandinavia and tried to model their future development based on climatic change data. Additionally, he also investigated the coastal areas of Vietnam and Southern China.

After his retirement at the IOW in 2008, Jan Harff moved to the University of Szczecin in Poland and took over a professorship in marine geosciences. This position allowed him to proceed with his international research projects, in particular in the coastal region of the South China (von Storch and Dietrich, 2017). Together with three colleagues from different geomarine disciplines, he edited the *Encyclopedia of Marine Geosciences* which in 2017 gained the “Mary B. Ansari Best Geoscience Research Resource Work Award” of the Geoscience Information Society (GSIS). Jan Harff was several times awarded: in 1989 with the Friedrich-Stammer Prize for geology in the former GDR, in 1998 with the Krumbein Medal of the International Association for Mathematical Geology (IAMG), in 2009 with the Serge-von-Bubnoff Medal of the German Geological Society (DGG), and in 2013 with the Chinese National Prize.

High-Order Spatial Stochastic Models

Roussos Dimitrakopoulos and Lingqing Yao

COSMO – Stochastic Mine Planning Laboratory, Department of Mining and Materials Engineering, McGill University, Montreal, Canada

Definition

High-order spatial stochastic models refer to a general non-Gaussian, nonlinear geostatistical modeling framework that consistently characterizes complex spatial architectures and facilitates the spatial uncertainty quantification of pertinent attributes of the earth sciences and engineering phenomena predicted from finite measurements. High-order spatial statistics such as spatial cumulants characterize non-Gaussian spatial random fields and facilitate the consistent description of complex nonlinear directional spatial patterns and the multiple point connectivity of extreme values. The corresponding high-order stochastic simulation approaches are data-driven and built upon the random field theory, beyond both the conventional second-order and the multipoint statistics based simulation frameworks.

Introduction

Traditional geostatistical simulation methods utilize covariance/variogram functions to characterize the so-called second-order spatial statistics and fully define the related multi-Gaussian random field. These traditional simulation methods have two major limitations. Firstly, most of the natural attributes are not compliant with Gaussian random fields and their symmetric bell-shape probability distributions as well as their maximum entropy aspects that conflict with the structured behavior of actual geological spatial patterns. In addition, second-order spatial statistics only capture the correlations between pairs of points and hence are unable to characterize more complex spatial structures that are typical in geological phenomena, such as curvilinear features, overlaying geological events, complex nonlinear patterns, directional multiple point periodicity, and so on. An early attempt to address the above shortcomings and to eliminate Gaussian assumptions was sequential indicator simulation (Journel 1989; Journel and Alabert 1989). This was followed by the introduction of multiple-point statistics (MPS) by Prof. Andre Journel at his Stanford Centre for Reservoir Forecasting, Stanford University, as opposed to the previously used two-point second-order statistics; this led to the development of the multiple-point simulation framework (Guardiano and Srivastava 1993; Journel 1993, 2003, 2005). The first

algorithm in this direction was SNESIM (Strébel 2000; Strébel 2002), a typical pixel-based MPS method, followed by several new patch-based MPS methods (Remy et al. 2009; Mariethoz et al. 2010; Mariethoz and Caers 2014; Gómez-Hernández and Srivastava 2021). Despite improvements in terms of reproducing spatial connectivity over the second-order stochastic simulation approaches, MPS methods require a training image (TI) as the source for the related inference (Guardiano and Srivastava 1993; Journel 1997, 2003, Journel and Zhang 2006) of multiple-point statistics. The term training image refers to an exhaustive image reflecting prior geological interpretations and acting as statistical analog to the underlying attributes of interest. This training-image driven nature generates a major limitation when MPS methods are applied in cases where statistical conflicts exist between the sample data available and the TI. This is a prominent issue when relatively reasonable sample data are available, as is typical in mining applications (Osterholt and Dimitrakopoulos 2007; Goodfellow et al. 2012). Figure 1 shows an example of variogram reproduction issues from a SNESIM application at a mineral deposit, where realizations reproduce the variogram of the training image but not that of the available data.

In addition, the experimentally selected multiple-point pattern (or moment) in MPS does not consider the consistency or relations between higher and lower order spatial moments over a series of orders used or facilitates data-driven connectivity of complex spatial patterns. Furthermore, while the MPS framework is more informed than those based on two-point or second-order statistics, the possibility of new approaches that are even more informed, given the wealth of information used in applications, remains to be addressed.

In recent years, a new high-order spatial modeling framework, based on measures of high-order complexity in spatial architectures, termed spatial cumulants, has been proposed. This approach not only facilitates dropping any distributional assumptions and data transformations but also develops spatial statistical models that are data-driven while capitalizing from integrating substantially more information from the underlying geological phenomena and related data. This includes complex, diverse, nonlinear, multiple-point directional or periodic patterns, advanced data-driven analytics, and the reconstruction of consistency between lower- and higher-order spatial complexity in the data used.

Cumulants are combinations of moments of statistical parameters that characterize non-Gaussian random fields. Research to date provides definitions, geological interpretations, and implementations of high-order spatial cumulants that are used, for example, in the high-dimensional space of Legendre polynomials to stochastically simulate complex, non-Gaussian, nonlinear spatial phenomena. The principal innovation, and a fundamentally challenging problem to address, is the development of mathematical models that

High-Order Spatial Stochastic Models, Fig. 1 Indicator variogram reproduction of SNESIM simulations (light gray) vs training image (dotted line) and data (solid line). (From Goodfellow et al. 2012)

move well beyond the “second-order models” to be more data-driven and consistent, as well as more informed than the previous MPS framework. The related mathematical models in turn open new avenues for the complex spatial modelling of geological uncertainty. The advantages of this work include (a) the absence of distributional assumptions and pre-/post-processing steps, e.g., data normalization or training image (TI) filtering; (b) the use of high-order spatial relations present in the available data to the simulation process (data-driven, not TI-driven), adding a wealth of additional information; and (c) the generation of complex spatial patterns to reproduce any data distribution and related high-order spatial cumulants, respecting the consistency of different high-order spatial relations. These developments define a mathematically consistent and more informed alternative to MPS, with substantial additional advantages (e.g., it is data-driven and reconstructs consistently the lower-order spatial complexity in the data used) for applications, particularly in cases where reasonably sized data sets are available. Notable is that the so-termed high-order stochastic simulation framework requires no fitting of parametric statistical models; similar to the MPS framework, high-order multiple-point relations are calculated directly from the available data sources during the simulation process, making the utilization of the related algorithms straightforward for the user. At the same time, the reproduction of related high-order spatial statistics by the resulting simulated realizations can be assessed through the cumulant maps mentioned in a subsequent section.

High-Order Spatial Cumulants

Spatial cumulants introduced in Dimitrakopoulos et al. (2010) for earth science and engineering problems are a

mathematical representation of high-order spatial statistics of a random field that quantify complex directional multiple point statistical interactions and characterize the spatial architectures of random fields. Related work in other fields includes signal processing (Nikias and Petropulu 1993; Zhang 2005; others), astrophysics (e.g. Gaztanaga et al. 2000), and image processing (Zetsche and Krieger 2001; Bouleminadjel et al. 2018).

Moments and cumulants are critical statistical concepts, given that the probability distribution of a random variable can be transformed accordingly as a moment-generating or cumulant-generating function. Let $(\Omega, \mathcal{I}, P)$ be a probability space; given a real-valued random variable, Z , as a measurable function defined on the sample space Ω with a probability density function $f_Z(z)$, the r th ($r \geq 0$) moment of Z is expressed as

$$\text{Mom}[Z, \dots, Z] = E[Z^r] = \int_{-\infty}^{+\infty} z^r f_Z(z) dz. \quad (1)$$

The moment-generating function (Rosenblatt 1985) of Z is defined by

$$M(w) = E[e^{wz}] = \int_{-\infty}^{+\infty} e^{wz} f_Z(z) dz. \quad (2)$$

The cumulant-generating function of Z is defined as the logarithm of the moment-generating function $M(w)$

$$K(w) = \ln(E[e^{wz}]). \quad (3)$$

The r th moment of Z can be obtained as the r th derivative of $M(w)$ at the origin through the Taylor expansion of the moment-generating function about the origin

$$\begin{aligned}
 M(w) &= E[e^{wz}] = E\left[1 + wZ + \dots + \frac{w^r Z^r}{r!} + \dots\right] \\
 &= \sum_{r=0}^{\infty} \frac{w^r \text{Mom}\left[\overbrace{Z, \dots, Z}^r\right]}{r!}.
 \end{aligned} \quad (4)$$

The cumulants of Z are the coefficients in the Taylor expansion of the cumulant-generating function, $K(w)$, about the origin

$$K(w) = \ln(E[e^{wz}]) = \sum_{r=0}^{\infty} \frac{w^r \text{Cum}\left[\overbrace{Z, \dots, Z}^r\right]}{r!}. \quad (5)$$

The relationship between the cumulants and moments can be further derived by extracting the coefficients of the two Taylor series (4) and (5) through differentiation.

Spatial cumulants extend the concept of cumulants to the multivariate probability distribution of a random field endowed with more complex spatial structures, similar in a way to how the covariance function extends the second-order moments to represent two-point spatial statistics. The spatial cumulants associated with any subset of random variables of the random field $Z(\mathbf{u})$ are statistical functions of distance vectors among the locations of the related random variables. The spatial configuration of an arbitrary set of random variables $Z(\mathbf{u}_0), Z(\mathbf{u}_1), \dots, Z(\mathbf{u}_n)$, of the random field $Z(\mathbf{u})$, can be uniquely determined by the so-called spatial template with a center node noted as $Z(\mathbf{u}_0)$ and the distance vectors $\mathbf{h}_1, \dots, \mathbf{h}_n$, defined as those vectors between each node other than $Z(\mathbf{u}_0)$ to the center node (Fig. 2). The r -th spatial cumulants of random variables within a spatial template can be expressed as $c_r^z(\mathbf{h}_1, \dots, \mathbf{h}_{r-1})$. While the relations between cumulants

High-Order Spatial Stochastic Models, Fig. 2 Spatial template of $Z(\mathbf{u}_0), Z(\mathbf{u}_1), \dots, Z(\mathbf{u}_n)$

and moments can be readily established through the generalization of Eqs. (4) and (5) to multivariate probability distributions, the spatial cumulants can be written as a combination of spatial moments and vice versa (Smith 1995; Dimitrakopoulos et al. 2010). For a zero-mean stationary random field, the second-order spatial cumulant corresponds to the covariance and is given by

$$c_2^z(\mathbf{h}) = E[Z(\mathbf{u})Z(\mathbf{u} + \mathbf{h})], \quad (6)$$

the third- and fourth-order spatial cumulants are defined respectively as

$$c_3^z(\mathbf{h}_1, \mathbf{h}_2) = E[Z(\mathbf{u})Z(\mathbf{u} + \mathbf{h}_1)Z(\mathbf{u} + \mathbf{h}_2)], \quad (7)$$

and

$$\begin{aligned}
 c_4^z(\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3) &= E[Z(\mathbf{u})Z(\mathbf{u} + \mathbf{h}_1)Z(\mathbf{u} + \mathbf{h}_2)Z(\mathbf{u} + \mathbf{h}_3)] \\
 &\quad - c_2^z(\mathbf{h}_1)c_2^z(\mathbf{h}_2 - \mathbf{h}_3) \\
 &\quad - c_2^z(\mathbf{h}_2)c_2^z(\mathbf{h}_3 - \mathbf{h}_1) \\
 &\quad - c_2^z(\mathbf{h}_3)c_2^z(\mathbf{h}_1 - \mathbf{h}_2).
 \end{aligned} \quad (8)$$

More specifically, spatial cumulants of order r ($r \geq 3$) consist of a combination of second-order spatial statistics and other spatial moments of order no greater than r .

The experimental computation of spatial cumulants is similar to that of experimental variograms, while the mathematical formulae are more sophisticated, as exemplified by Eqs. (7) and (8). The calculation of experimental spatial cumulants can be carried out either on an exhaustive training image or on irregularly distributed samples by allowing a certain tolerance in the corresponding spatial template (Fig. 3). A computational algorithm and related computer program for high-order spatial cumulants is available in the

High-Order Spatial Stochastic Models, Fig. 3 An example of irregular template for third-order cumulant calculation (from Dimitrakopoulos et al. 2010)

High-Order Spatial Stochastic Models, Fig. 4 Interpretations of the high positive anomalies in the third-order map. (1.a) to (2.a) explains, respectively, the high anomalies in (1.b) to (2.b) from the interactions

between the black zones in the red rectangles (from Mustapha and Dimitrakopoulos 2010a, b)

public domain (Mustapha and Dimitrakopoulos 2010a, b). This algorithm provides a tool to generate high-order cumulant maps as a typical application of spatial cumulants to delineate the spatial patterns of natural attributes. Figure 4 shows an example of third-order cumulant maps to characterize the interactions among attributes at multiple locations.

In general, high-order spatial cumulants provide a statistical entity to capture the spatial architecture of natural attributes, including spatial directionality, periodicity, homogeneity, and connectivity, in multiple directions and among multiple points. An additional property worth noting is that the spatial cumulants of the Gaussian random field vanish for orders higher than 2, indicating that high-order spatial cumulants are essential to characterize the non-Gaussian features of natural phenomena.

High-Order Simulation Methods

A general framework for generating realizations from a random field is the sequential simulation framework (Journel 1989, 1994; Deutsch and Journel 1992; Gómez-Hernández and Srivastava 2021), which has been applied to many popular stochastic simulation methods, as well as to the high-order stochastic simulation method (*hosim*) presented herein. Consider a random field $Z(\mathbf{u})$, $\mathbf{u} \in R^d$ ($d = 1, 2, 3$), consisting of a family of random variables as $Z(\mathbf{u}_1), Z(\mathbf{u}_2), \dots, Z(\mathbf{u}_N)$ on a finite discretized domain, with a multivariate probability density function denoted as $f(z_1, z_2, \dots, z_N)$. If an initial data set denoted as $\Lambda_0 = \{\zeta_1, \dots, \zeta_n\}$ is available, then the joint probability density function (PDF) can be decomposed (Johnson 1987) as

$$f(z_1, z_2, \dots, z_N | \Lambda_0) = f(z_1 | \Lambda_0) f(z_2 | \Lambda_1) \cdots f(z_N | \Lambda_{N-1}), \quad (9)$$

where $\Lambda_{i+1} = \{z_i\} \cup \Lambda_i$, $i = 0, 1, \dots, N-1$. The decomposition of joint PDF in Eq. (9) allows the generation of a realization from the related random field by sampling from a sequence of conditional probability distributions with density $f(z_i | \Lambda_{i-1})$, $i = 1, \dots, N$. In practice, the conditioning data Λ_i are often confined to a limited neighborhood considering the computational efficiency as well as the statistical irrelevancy of the farther data due to the so-called screen effect (Dimitrakopoulos and Luo 2004).

The main difference and advantage of high-order stochastic simulation from other previously developed simulation approaches, including MPS methods, is that they are not only free of distributional assumptions but also fully account for the high-order spatial statistics from the available data in a consistent, data-driven, and substantially more complete and informed manner. As the related technical literature shows (Minniakhmetov et al. 2018), the joint PDF of the random field is approximated by an orthogonal polynomial expansion series. Given a complete system of orthogonal functions, $\varphi_1(z)$, $\varphi_2(z)$, $\dots$, defined on interval $[a, b]$, then $f(z)$ can be approximated as

$$f(z) \approx \sum_{m=0}^{\omega} L_m \varphi_m(z), \quad (10)$$

where ω is the maximum order of the polynomials in the truncated expansion series. Similarly, an $(n+1)$ -variate piecewise continuous function $f(z_0, z_1, z_2, \dots, z_n)$ can be approximated as

$$f(z_0, z_1, \dots, z_n) \approx \sum_{m_0=0}^{\omega_0} \sum_{m_1=0}^{\omega_1} \cdots \sum_{m_n=0}^{\omega_n} L_{m_0, m_1, \dots, m_n} \varphi_{m_0}(z_0) \varphi_{m_1}(z_1) \cdots \varphi_{m_n}(z_n). \quad (11)$$

Especially, consider $f(z_0, z_1, \dots, z_n)$ as the joint PDF of random variables, $Z(\mathbf{u}_0)$, $Z(\mathbf{u}_1)$, $\dots$, $Z(\mathbf{u}_n)$, defined on a random field $Z(\mathbf{u})$; the coefficients $L_{m_0, m_1, \dots, m_n}$ can be derived as high-order moments according to the orthogonal property as (Minniakhmetov et al. 2018)

$$L_{m_0, m_1, \dots, m_n} \approx E[\varphi_{m_0}(z_0) \varphi_{m_1}(z_1) \cdots \varphi_{m_n}(z_n)] \\ \approx \frac{1}{N_{h_1, h_2, \dots, h_n}} \sum_{k=1}^{N_{h_1, h_2, \dots, h_n}} \varphi_{m_0}(\zeta_0^k) \varphi_{m_1}(\zeta_1^k) \cdots \varphi_{m_n}(\zeta_n^k). \quad (12)$$

The approximation in Eq. (12) also shows the experimental computation of the coefficients $L_{m_0, m_1, \dots, m_n}$, where $N_{h_1, h_2, \dots, h_n}$ is the number of replicates retrieved from the available data and $\zeta_0^k, \zeta_1^k, \dots, \zeta_n^k$ are the corresponding attribute values given a spatial template of distance vectors as $\mathbf{h}_1, \dots, \mathbf{h}_n$.

Note that the early approach in Mustapha and Dimitrakopoulos (2010b) uses Legendre polynomials as the orthogonal bases to develop the approximation of the joint PDF in Eq. (11). However, the numerical stability of approximation by Legendre polynomial series is influenced by the available data. Thus, Minniakhmetov et al. (2018) propose the use of Legendre-like splines to replace the Legendre polynomials as the orthogonal bases. This method is shown to perform better in the reproduction of spatial connectivity of extreme values, which are more likely to cause numerical instability in the expansion series.

From the perspective of computational efficiency, a new computational model of high-order simulation has been proposed to replace the explicit calculation of spatial cumulants in the Legendre polynomial expansion series by a simple kernel-like function that can be computed in polynomial time (Yao et al. 2018). A statistical learning framework of high-order simulation is also developed based on a new proposed concept of spatial Legendre moment kernel so that the joint PDF of the random field is estimated in a stable solution domain through a learning algorithm, with possible extension to develop a TI-free high-order simulation (Yao et al. 2020; Yao et al. 2021a, 2021b). Other advancements in high-order simulation methods include block-support high-order simulation (de Carvalho et al. 2019), joint high-order simulation of multivariate attributes (Minniakhmetov and Dimitrakopoulos 2016), and high-order simulation of categorical data (Minniakhmetov and Dimitrakopoulos 2017, 2021).

An algorithmic description of high-order stochastic simulation can be summarized as the following:

1. Draw a random path to visit all the nodes to be simulated.
2. Approximate the local conditional probability density function of each node based on Legendre polynomial expansion series in Eqs. (11) and (12) by computing the coefficients from the experimental high-order spatial statistics, which are calculated directly from the data and TI used.
3. Draw a random value from the local conditional probability density function for the simulated node and add it into the conditioning data.
4. Repeat from step (1) until all the nodes in the random path have been visited.

Examples

High-order sequential simulations (*hosim*) have been used in different applications, including for generating realizations of mineral deposit grades (e.g., Minniakhmetov and Dimitrakopoulos 2016; Minniakhmetov et al. 2018; de Carvalho et al. 2019) for mine production planning and the heterogeneity representation for subsurface flow (e.g.,

High-Order Spatial Stochastic Models, Fig. 5 Sections of a simulated realization using *hosim* from the gold deposit: (a) horizontal sect. 1; (b) horizontal sect. 2; and (c) a vertical section. Colors indicate grades in g/t. (From Minniakhmetov et al. 2018)

High-Order Spatial Stochastic Models, Fig. 6 The same sections as in Fig. 5 but from simulated realization of the gold deposit using *sgssim*: (a) horizontal sect. 1; (b) horizontal sect. 2; and (c) a vertical section. Colors indicate grades in g/t. (From Minniakhmetov et al. 2018)

Mustapha et al. 2011; Tamayo-Mas et al. 2016). To demonstrate the main aspects of high-order spatial statistics and simulation methods discussed in the previous sections, as well as the ability of high-order sequential simulation to capture data-driven spatial complexity, some examples from an application at a typical gold deposit (Minniakhmetov et al. 2018) are included in this section.

The data available in an operating gold mine cover an area around 4 km² and include 288 exploration drillholes; a training image is available from the blasthole samples. High-order sequential simulation is used to generate realizations of the gold grades. The high-order statistics needed are directly calculated from the available data and TI employed by the *hosim* algorithm; this is analogous to the approach used by MPS simulation algorithms; no fitting of parametric high-order statistical models is part of the related process. Figure 5 shows cross-sections from a realization generated using high-order sequential simulation, while Fig. 6 shows, for reasons of comparison, the same sections generated using the conventional sequential Gaussian simulation (*sgssim*). The differences in overall patterns are clear and as expected.

With respect to the reproduction of data histograms and variograms, realizations from both *hosim* and *sgssim* show a reasonable reproduction. As expected, high-order simulations also reproduce high-order spatial data statistics. For example, Fig. 7 shows the fourth-order cumulant maps of the data, the training image used, a *hosim* realization, and a realization from *sgssim*. Last, as seen in the visualization of the cross-sections in Figs. 5 and 6, *hosim* generates a better reproduction of the spatial connectivity of extreme values than *sgssim*, which is also shown in the connectivity measures for the 99th gold grade percentile in Fig. 8.

Note that comparisons of simulated realizations generated with high-order sequential simulation approaches to realizations generated with the MPS simulation method *filtersim* (Remy et al. 2009) also show a better performance of the high-order statistics framework with respect to integrating and reproducing complex spatial patterns (e.g., Mustapha et al. 2011; Yao et al. 2018).

High-Order Spatial Stochastic Models, Fig. 7 The fourth-order spatial cumulant maps of (a) the drill-hole data, (b) the training image (TI), (c) a simulation using *hosim*, and (d) a simulated realization using *sgsim*. (From Minniakhmetov et al. 2018)

Summary and Conclusions

High-order stochastic simulation provides a general, data-driven sequential simulation framework free of distributional assumptions that characterize spatially distributed and varying natural phenomena with a diversity of complex spatial textures and architectures. The fundamental concepts in high-order sequential simulation are (i) the definition of high-order spatial statistics, such as spatial cumulants and (ii) the estimation of multivariate probability distributions of a random field based on mathematical models that incorporate the high-order spatial statistics.

The introduction and use of high-order spatial statistics and, more specifically, spatial cumulants is critically important and a major advancement compared to the previously developed framework of multiple point statistics and related simulation approaches. As noted in the introduction, spatial

cumulants characterize non-Gaussian spatial random fields and exhibit complex nonlinear directional spatial patterns and multiple point connectivity of extreme values, while making the subsequent simulation process consistent over a series of orders and facilitating a data-driven process. This consistency is not the case with MPS simulation methods, which are driven by a statistically less informed and arbitrarily selected pattern or moment from a training image. The data-driven nature of spatial cumulant inference facilitates (i) the development of high-order sequential stochastic simulation models, such as the ones mentioned above; (ii) the optimization of data processing and analytics, including the mitigation of the statistical conflicts among samples and other additional information such as the TI; and (iii) the utilization of advanced learning algorithms constrained to the high-order spatial statistics of the available data. It should be stressed that the high-order stochastic simulation framework is

The connectivity along x (left subfigure) and y (right subfigure) for 99% percentile: the TI (blue line), P50 statistics for *hosim* simulations (solid red line), P10 and P90 statistics for *hosim* simulations (dashed red line), and P50 statistics for simulations using *sgsim* (grey line). (From Minniakhmetov et al. 2018)

nonparametric; that is, spatial cumulants or other type of high-order spatial statistics needed are calculated directly during the high-order sequential simulation process, and no parametric model fitting is introduced; thus making the use of related algorithms very practical and user friendly.

Note that computer programs for both calculating high-order cumulants as well as high-order sequential simulation with the method described herein are available in the public domain (Mustapha and Dimitrakopoulos 2010a, b; Minniakhmetov et al. 2018). The practice of high-order sequential simulation is, evidently, neither more complex nor simpler than other modern geostatistical simulation frameworks.

Hilbert Space

Daisy Arroyo

Department of Statistics, Universidad de Concepción, Concepcion, Chile

Definition

A Hilbert space is an inner product space that is complete with respect to the norm induced by the inner product and is commonly denoted as H . Completeness in this context means that each Cauchy sequence of elements in space converges to one element in space, in the sense that the norm of differences approaches to zero. Each Hilbert space is therefore also a Banach space (but not the reverse).

Introduction

The methods of linear algebra study the concepts of spaces and apply to their transformations, operators, projectors, etc. In abstract spaces, elements are called a set of points, stochastic variables, vectors, and functions that have certain properties. In particular, the Euclidean spaces of n dimensions and the Hilbert spaces of infinite dimensions are of great importance. The Hilbert space concept is a generalization of the Euclidean space. This generalization allows algebraic and geometric notions and techniques applicable to two- and three-dimensional spaces to be extended to arbitrary-dimensional spaces, including infinite-dimensional spaces. There are no restrictions on how vectors should look in Hilbert space: they can be three-dimensional vectors, functions, or infinite sequences.

The Venn diagram below summarizes the different types of spaces and their relationship to the Hilbert space (Fig. 1).

Remembering that:

- A vector space is a set X on which two operations are defined called vector addition that takes each ordered pair (x, y) of elements of X to an element $x + y \in X$, and scalar multiplication that takes a pair (λ, x) to an element $\lambda x \in X$, for $\lambda \in \mathbb{R}$ (or $\mathbb{C}$) and $x \in X$. The vector addition must satisfy the following conditions:

Hilbert Space, Fig. 1 Venn diagram with the different types of spaces

- (a) $x + y = y + x$, for all $x, y \in X$ (commutative law).
- (b) $x + (y + z) = (x + y) + z$, for all $x, y, z \in X$ (associative law).
- (c) The set X contains an additive identity element, denoted by 0 , such that for any vector $x \in X$, $x + 0 = x$.
- (d) For each $x \in X$, there is an additive inverse $-x \in X$, such that $x + (-x) = 0$.

On the other hand, the scalar multiplication must satisfy the following conditions:

- (a) $\lambda(x + y) = \lambda x + \lambda y$, for all $x, y \in X$, and $\lambda \in \mathbb{R}$ (or $\mathbb{C}$) (distributive law)
 - (b) $(\lambda + \mu)x = \lambda x + \mu x$, for $x \in X$, and $\lambda, \mu \in \mathbb{R}$ (or $\mathbb{C}$)
 - (c) $\lambda(\mu x) = (\lambda\mu)x$, for $x \in X$, and $\lambda, \mu \in \mathbb{R}$ (or $\mathbb{C}$)
 - (d) For all $x \in X$, $1x = x$ (multiplicative identity)
- An inner product space is a vector space X along with an inner product on X , where an inner product is a function that takes each ordered pair (x, y) of elements of X to a number $\langle x, y \rangle \in \mathbb{R}$ (or $\mathbb{C}$) and has the following properties:
 - (a) $\langle x, x \rangle \geq 0$, for all $x \in X$, and $\langle x, x \rangle = 0$ if only if $x = 0$ (positive definiteness)
 - (b) $\langle x + y, z \rangle = \langle x, z \rangle + \langle y, z \rangle$, for all $x, y, z \in X$ (additivity)
 - (c) $\langle \lambda x, y \rangle = \lambda \langle x, y \rangle$, for all $\lambda \in \mathbb{R}$ (or $\mathbb{C}$), and all $x, y \in X$ (homogeneity)
 - (d) $\langle x, y \rangle = \overline{\langle y, x \rangle}$, for all $x, y \in X$ (conjugate symmetry), where the bar denotes the complex conjugate of a complex number

- A normed space is a vector space X endowed with a function

$$\|\cdot\| : X \rightarrow [0, \infty),$$

called the norm on X , with the following properties:

- (a) $\|\lambda x\| = |\lambda| \|x\|$, for all $x \in X$, $\lambda \in \mathbb{R}$ (homogeneity)
 - (b) $\|x + y\| \leq \|x\| + \|y\|$, for all $x, y \in X$ (triangle inequality)
 - (c) $\|x\| = 0$ if only if $x = 0$ (positive definiteness)
- A Banach space is a normed vector space X with the property that each Cauchy sequence $\{x_k\}_{k=1}^{\infty}$ in X converges toward some $x \in X$. In cases where the relevant vector space X is a subspace of a larger space, it is important to note that there are two additional requirements: each Cauchy sequence of elements in X must be convergent and the limit of the Cauchy sequence must belong to X .

Natural examples of Banach spaces are $\mathbb{R}^n$ and $\mathbb{C}^n$.

The Banach space $L^p(\mathbb{R})$, for $1 < p < \infty$, is the space of functions f for which $|f|^p$ is integrable:

$$L^p(\mathbb{R}) := \left\{ f : \mathbb{R} \rightarrow \mathbb{C} \text{ such that } \int_{-\infty}^{\infty} |f(x)|^p < \infty \right\}.$$

A Hilbert space is a complete inner product space. Every Hilbert space is a Banach space with respect to the norm.

Historical Material

In the first decade of the twentieth century, the German mathematician David Hilbert first described this space in his work on integral equations and Fourier series. Indeed, the definition of a Hilbert space was first given by von Neumann, rather than Hilbert, the origin of the designation “der abstrakte Hilbertsche Raum” in his famous work on unbounded Hermitian operators published in 1929. The name *Hilbert space* was soon adopted by others, for example, Hermann Weyl in his book *The Theory of Groups and Quantum Mechanics* published in 1931. After Hilbert’s research, the Austrian-German mathematician Ernst Fischer and the Hungarian mathematician Frigyes Riesz (1907; Fischer 1907) showed that integrable square functions could also be considered as points in a complete inner product space that is equivalent to the Hilbert space.

Examples

All finite-dimensional inner product spaces are Hilbert spaces, for example, Euclidean space with the ordinary dot product. Other examples of Hilbert spaces include spaces of square-integrable functions, spaces of sequences, Sobolev spaces consisting of generalized functions, and Hardy spaces of holomorphic functions. Infinite dimension examples are much more important in applications. Below are some of the most popular Hilbert spaces.

The Hilbert Space $L^2(\mathbb{R}^d)$

Among the $L^p(\mathbb{R}^d)$ -spaces, the case $p = 2$ is very important. The collection of square integrable functions in $\mathbb{R}^d$, $L^2(\mathbb{R}^d)$, is formed by all measurable functions of complex value f such that

$$L^2(\mathbb{R}^d) = \left\{ f : \mathbb{R}^d \rightarrow \mathbb{C} \text{ such that } \int_{\mathbb{R}^d} |f(x)|^2 dx < \infty \right\}.$$

The inner product is defined as

$$\langle f, g \rangle = \int_{\mathbb{R}^d} f(x) \overline{g(x)} dx, \forall f, g \in L^2(\mathbb{R}^d),$$

and the norm is defined as

$$\|f\| = \left(\int_{\mathbb{R}^d} |f(x)|^2 dx \right)^{1/2}.$$

Similarly, any E measurable subset of $\mathbb{R}^d$ with $m(E) > 0$ (measure of E must be positive), that is, the space of square integrable functions that are supported on E is a Hilbert space, denoted by $L^2(E)$.

The Hilbert Space $\mathbb{C}^n$

The standard inner product in this space is given by (Rudin 1986)

$$\langle x, y \rangle = \sum_{i=1}^n x_i \overline{y_i},$$

where $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$, with $x_i, y_i \in \mathbb{C}$, and the norm is defined as

$$\|x\| = \left(\sum_{i=1}^n |x_i|^2 \right)^{1/2}.$$

This space is complete, therefore is a finite-dimensional Hilbert space.

The Hilbert Space $l^2(\mathbb{Z})$

Defined as:

$$l^2(\mathbb{Z}) = \left\{ (\dots, x_{-2}, x_{-1}, x_0, x_1, \dots) : x_i \in \mathbb{C}, \sum_{n=-\infty}^{\infty} |x_n|^2 < \infty \right\}.$$

The space $l^2(\mathbb{Z})$ is a complex linear space. The inner product is given by

$$\begin{aligned} \langle x, y \rangle &= \sum_{n=-\infty}^{\infty} x_n \overline{y_n}, \text{ where} \\ x &= (\dots, x_{-2}, x_{-1}, x_0, x_1, \dots) \text{ and} \\ y &= (\dots, y_{-2}, y_{-1}, y_0, y_1, \dots), \end{aligned}$$

and the norm is defined as

$$\|x\| = \left(\sum_{n=-\infty}^{\infty} |x_n|^2 \right)^{1/2}.$$

All infinite dimensional (separable) Hilbert spaces are $l^2(\mathbb{Z})$ (Stein and Shakarchi 2005). The space $l^2(\mathbb{N})$ of square-summable sequences $\{x_n\}_{n=1}^{\infty}$ is defined in an analogous way.

The Hilbert Space $\mathbb{C}^{m \times n}$

The space of all $m \times n$ matrices with complex entries. The inner product on $\mathbb{C}^{m \times n}$ is defined as

$$\langle A, B \rangle = \text{tr}(A^* B) = \sum_{i=1}^m \sum_{j=1}^n a_{ij} \overline{b_{ij}},$$

where $A = (a_{ij})$, $B = (b_{ij})$ are matrices, tr denotes the trace, and $*$ denotes the Hermitian conjugate of a matrix (the complex-conjugate transpose). The corresponding norm

$$\|A\| = \left(\sum_{i=1}^m \sum_{j=1}^n |a_{ij}|^2 \right)^{1/2}$$

is called the Hilbert-Schmidt norm.

The properties of orthogonality and projection in Hilbert spaces, which are of great interest in applications, are briefly described below.

Orthogonality

The inner product structure of a Hilbert space allows introducing the concept of orthogonality (Rudin 1986), which makes it possible to visualize vectors and linear subspaces of Hilbert space in a geometric way.

If x, y are vectors in a Hilbert space H , then x and y are orthogonal (denoted as $x \perp y$) if $\langle x, y \rangle = 0$. The subsets A and B are orthogonal (denoted as $A \perp B$) if $x \perp y$ for all $x \in A$ and for all $y \in B$. The orthogonal complement (denoted as $A^\perp$) of a subset A is the set of vectors orthogonal to A :

$$A^\perp = \{x \in H \mid x \perp y \text{ for all } y \in A\}.$$

The orthogonal complement of a subset of a Hilbert space is a closed linear subspace.

Projection

Let P be a closed linear subspace of a Hilbert space H , then (Fig. 2):

- (a) For each $x \in H$, there is a unique closest point $y \in P$ such that

Hilbert Space, Fig. 2 y is the point in P closest to x

$$\|x - y\| = \min_{z \in P} \|x - z\|.$$

- (b) The point $y \in P$ closest to $x \in H$ is the unique element of P with the property that $(x - y) \perp P$.

Applications

Hilbert spaces are the most important tools in the theories of partial differential equations, quantum mechanics, Fourier analysis, and ergodicity. Hilbert spaces serve to clarify and generalize the concept of Fourier expansion and certain linear transformations such as the Fourier transform. The Fourier series are a useful tool for the representation and approximation of periodic functions using trigonometric functions.

Each of following Hilbert space has a type of Fourier analysis associated with it:

- $L^2([a, b]) \rightarrow$ Fourier series
- $l^2([0, n - 1]) \rightarrow$ discrete Fourier transform
- $L^2(\mathbb{R}) \rightarrow$ Fourier transform
- $l^2(\mathbb{Z}) \rightarrow$ discrete time Fourier transform

The Hilbert space $L^2(\mathbb{R})$ plays a central role in many areas of science; for example, in signal processing, many time-varying signals are interpreted as functions in $L^2(\mathbb{R})$, and in quantum mechanics, the term “Hilbert space” simply means $L^2(\mathbb{R})$. For the case of $L^2([-\pi, \pi])$, the Fourier series is an infinite sum of functions $\sin(n\pi)$ and $\cos(n\pi)$, that is, oscillations with frequencies $\frac{n}{2\pi}$, with $n = 0, 1, 2, \dots$

In the 1920s von Neumann realized that Hilbert spaces are the natural setting for quantum mechanics, where a particle is confined to move in a straight line between two parallel walls. This particle at each instant in time t is described by an element $\varphi(\cdot, t) \in L^2([0, M])$, that is, a vector in the Hilbert

space of square-integrable, complex-valued function on the interval $[0, M]$, where M is the distance between the walls and the function φ is called the wave function of the particle.

In probability theory, Hilbert spaces arise naturally. A random experiment is modeled mathematically by a space Ω (sample space) and a probability measure P on Ω . Each point $\omega \in \Omega$ corresponds to a possible outcome of the experiment. An event A is a measurable subset of Ω . The probability measure P associates each event A with a probability $P(A)$, where $0 \leq P(A) \leq 1$ and $P(\Omega) = 1$. A random variable X is a measurable function $X : \Omega \rightarrow \mathbb{C}$, which maps each outcome in ω to a complex number (or real number). The expected value $\mathbb{E}[X]$ of a random variable X is the mean, or integral, of the random variable X with respect to the probability measure P , that is

$$\mathbb{E}[X] = \int_{\Omega} X(\omega) dP(\omega).$$

On the other hand, a random variable X is said to be second order if $\mathbb{E}[X^2] < \infty$. The set of second-order random variables forms a Hilbert space with respect to the inner product

$$\langle X, Y \rangle = \mathbb{E}[X\bar{Y}].$$

The space of second-order random variables may be identified with the space $L^2(\Omega, P)$ of square-integrable functions on (Ω, P) , with the inner product

$$\langle X, Y \rangle = \int_{\Omega} X(\omega) \overline{Y(\omega)} dP(\omega).$$

In geostatistics, one can find the Hilbert spaces of random fields (Chilès and Delfiner 2012). Consider a family of complex-valued random variables X defined on a probability space (Ω, A, P) and having finite second-order moments (Chilès and Delfiner 2012)

$$\mathbb{E}[|X|^2] = \int |X(\omega)|^2 P(d\omega) < \infty.$$

These random variables constitute a Hilbert space denoted $L^2(\Omega, A, P)$, with its inner product $\langle X, Y \rangle = \mathbb{E}[X\bar{Y}]$ (the upper bar denotes complex conjugation) and its norm $\|X\| = \sqrt{\mathbb{E}[|X|^2]}$. In this Hilbert space, two random variables are orthogonal when they are uncorrelated ($\langle X, Y \rangle = \mathbb{E}[X\bar{Y}] = 0$).

In a Hilbert space, the orthogonal projection of X onto a closed linear subspace K can be defined as the unique point X_0 in the subspace closest to X (Chilès and Delfiner 2012; Halmos 1951):

$$X_0 = \arg \min_{Y \in K} \|X - Y\| \Leftrightarrow \langle X - X_0, Y \rangle = 0, \text{ for all } Y \in K.$$

Since $X_0 \in K$, it satisfies $\langle X - X_0, X_0 \rangle = 0$, considering the triangular inequality we have

$$\|X - X_0 + X_0\|^2 = \|X - X_0\|^2 + \|X_0\|^2.$$

Or equivalently

$$\|X - X_0\|^2 = \|X\|^2 - \|X_0\|^2.$$

This result is used in kriging theory.

Conclusions

The Hilbert spaces are Banach spaces with a norm that is derived from an inner product, which is used to introduce the notion of orthogonality. The Hilbert spaces have several applications which arise naturally, mainly in physics and mathematics.

Horton, Robert Elmer

Keith Beven

Lancaster University, Lancaster, UK

Fig. 1 Robert Elmer Horton (from Merrill Bernard 1945), from Bulletin American Meteorological Society

Biography

Robert Horton is recognized as one of the foremost hydrologists of the twentieth century. He was born in 1875 in Parma, Michigan and obtained a BSc degree from Albion College, Michigan in 1897 (which later also awarded him an honorary Ph.D. in 1932). Horton's professional work began under the direction of his uncle, George Rafter, a prominent civil engineer who had earlier worked on the Erie Canal. For better streamflow measurements, Rafter had commissioned laboratory weir studies at Cornell. Horton analyzed and summarized the results. This initial work was then considerably extended when Horton joined the US Geological Survey in 1900. The resulting publications became the standard US work on the subject.

This led on to a program of extensive stream gaging on New York streams and work on baseflow which he recognized was dominated by groundwater. He also started to focus on the role of infiltration in controlling both recharge to groundwater and surface runoff. He subsequently came to view the soil surface as a "separating surface" between water that either infiltrated and would later become baseflow or return to the atmosphere as evapotranspiration, and water in excess of the infiltration capacity of the soil surface that would become surface runoff and could contribute quickly to the stream hydrograph (Horton 1933). He proposed an equation for infiltration rates at the surface that would then allow

the calculation of rates of surface runoff given rainfall inputs (Horton 1939). This was used by Horton in his later work as a hydrologic consultant, based at the Horton Hydrological Laboratory near Voorheesville, New York. It was rapidly adopted by many others as a useful tool in flood prediction to the extent that the concept became known as "Hortonian overland flow."

Horton's view of infiltration was, however, much more sophisticated than has been commonly appreciated. He argued that infiltration capacities were controlled by surface rather than profile controls, and that these would change over time both within an event due to "extinction phenomena," such as the displacement of soil particles blocking larger pores, and between events. He also recognized the role of air pressure, cracks and macropores, on infiltration and the variability of soil characteristics in runoff production. Interestingly, analyses suggest that he might not have seen widespread surface runoff on his own experimental catchment at the Horton Laboratory very often (Beven 2004). This did not stop the concepts getting widely used (even to the present day).

Throughout his career, Horton was interested in flood generation and prediction, including publishing on the meteorological aspects of intense storms. He was one of the first to try to estimate "maximum possible rainfalls" for different places, which when combined with the infiltration theory might allow a maximum flood to be estimated. He showed how some observed events had approached these limits.

In terms of mathematical geoscience, Horton published a number of interesting analytical solutions for hydrological processes during his career, but his most significant contribution appeared in the Bulletin of the Geological Society of America just 1 month before his death in 1945 (Horton 1945). This is an extensive treatise of 95 pages that deals with the implications of his surface runoff theory on the erosional development of hillslopes and drainage basins. It is a remarkable seminal achievement that later stimulated other hydrologists and geomorphologists in the "quantitative revolution" in Geography that started in the late 1960s and the analysis of landscapes as fractal surfaces in the 1980s.

Horton's importance to both hydrology and meteorology is recognized by both the Horton Medal of the American Geophysical Union and the Horton Lecture of the American Meteorological Society.

Howarth, Richard J.

J. M. McArthur

Earth Sciences, UCL, London, WC1E 6BT, UK

Fig. 1 Richard J. Howarth, courtesy of Prof. Howarth

Biography

Richard J. Howarth was born in Southport, UK, in 1941. After gaining a B.Sc. in geology in 1963 from Bristol University he stayed on to undertake a Ph.D. (completed 1966) on the Irish extension of the Cryogenian Port Askaig Tillite formation. The research involved statistical calibrations for the first XRF spectrometer to be installed in a British geology department, and the use of factor analysis for the interpretation of geochemical and other data. The period 1966–1968 was spent in

The Hague, The Netherlands, with Bataafse Petroleum Maatschappij (Shell), where he undertook statistical analysis relating the geology of the World's sedimentary basins to their hydrocarbon production.

Returning to the UK in 1968 for family reasons, he joined John Webb's Applied Geochemistry Research Group, in the Department of Geology at Imperial College of Science & Technology, London, where he worked until 1985. His research at Imperial College was initially concerned with analytical methodologies and with mapping and interpreting regional geochemical survey data for mineral exploration, geological, and epidemiological purposes. He worked with chemist Michael Thompson to develop statistical techniques and procedures, which have now become standard, for quality assurance of analytical data used for regional geochemical mapping (e.g., Thompson and Howarth 1973). The software he developed while at Imperial underpinned production of pioneering regional geochemical atlases of Northern Ireland, of England and Wales (Webb et al. 1978), and elsewhere. He also worked with a team under George Koch Jr., of the University of Georgia, USA (1978–84), on the statistical interpretation of data from the US National Uranium Resource Evaluation Program. Much of this accumulated experience was summarized in Howarth (1983).

In 1985 he joined the British Petroleum group as a senior consultant in BP Research, Sunbury, where his research and advisory duties encompassed biostratigraphy, chemostratigraphy, estimation of hydrocarbon reserves, petrophysical data analysis, laboratory quality-control, well-inflow performance monitoring, and numerous other matters. In the course of this, he collaborated with P.C. Smalley and A. Higgins and others to develop Sr-isotope stratigraphy, work later continued with others at University College London over the next 23 years (e.g., McArthur et al. 2001).

Since 1993, he has held the honorary position of Professor in Mathematical Geology in the Department of Earth Sciences, University College London. During this time his interests broadened to include writings on the history of geology and geophysics (e.g., Howarth 2017). His wide reading of the literature of applied statistics enabled him to cross discipline boundaries and introduce techniques which were new to geology, for example, empirical discriminant function, non-linear mapping, power transform, and various estimators of uncertainty.

He has been awarded the Murchison Fund of The Geological Society of London (1987), William Christian Krumbein Medal of the International Association for Mathematical Geology (2000) for contributions to mathematical geology, and the Sue Tyler Friedman Medal of the Geological Society of London (2016) for contributions to the history of geology.

Hurst Exponent

Sid-Ali Ouadfeul¹ and Leila Aliouane²

¹Algerian Petroleum Institute, Sonatrach, Boumerdes, Algeria

²LABOPHT, Faculty of Hydrocarbons and Chemistry, University of Boumerdes, Boumerdes, Algeria

Definition of the Hölder Exponent

The singularity exponent at a point x_0 can be expressed by an exponent called the Hölder exponent, and this exponent is defined as follows:

The Hölder exponent of the distribution f at point (x_0) is the largest h , whose f is Lipschitzian with exponent h at point (x_0) . It means, there exists a constant C and a polynomial of $P_n(x)$ of n order such that for all x belonging to the neighborhood of x_0 we have:

$$|f(x) - P_n(x - x_0)| \leq C|x - x_0|^h \quad (1)$$

If $h(x_0) \in]n, n + 1[$ we can easily demonstrate that at point x_0 the polynomial $P_n(x)$ corresponds to the Taylor series of f at point x_0 , $h(x_0)$ measures how the distribution f is irregular at x_0 , it means:

$h(x_0)$ is very high $\Leftrightarrow f$ is regular.

In the most cases $h(x_0) = h + 1$ for the primitive of f , and $h(x_0) = h - 1$ for the derivative.

Definition of the Hurst Exponent

If the Hölder exponent of a function f is constant per interval ($h_i = H_j$ for the interval $[a_j, b_j]$, $i = 0, 1, 2, \dots, N_j$, $j = 1, 2, 3, \dots, M$), H_j are the Hurst exponents.

H_j measures the global regularity per interval.

Estimated Hurst exponent H of the function f is able to say that f is an anti-correlated random walk ($H < 1/2$: anti-persistent random walk), or positively correlated ($H > 1/2$: persistent random walk). $H = 1/2$ corresponds to classical Brownian motion (Audit et al. 2004).

The Multifractal Brownian Motion

Let $H \in]0, 1[$, the fractional Brownian motion (fBm) is defined as a centered Gaussian process $(B_t^H)_{t \geq 0}$ with covariance function $RH(t, s) = E(B_t^H B_s^H) = 1/2(t^{2H} + s^{2H} - |t - s|^{2H})$. The index H is called the Hurst exponent and it determines the main properties of the process B^H , such as a self-similarity and a regularity of the sample paths and a long memory. Figure 1 shows an example of fractional Brownian motion realization with 1024 samples and a Hurst exponent $H = 0.60$.

Methods of Estimation of the Hurst Exponent

Spectral Density Method

The Fourier transform of a fBm function $f(t)$ is given by:

$$FT[f(t)] = \int_{-\infty}^{+\infty} f(t)e^{-2\pi ift} dt = F(f) = A(f) + jB(f) \quad (2)$$

$$F(f) = |F(f)|e^{j\varnothing(f)} \quad (3)$$

$|F(f)|$ and $\varnothing(f)$ are the spectra of amplitude and phase, these spectra are given by:

$$|F(f)| = \sqrt{A(f)^2 + B(f)^2} \quad (4)$$

$$\varnothing(f) = \begin{cases} \arctg\left(\frac{B(f)}{A(f)}\right) & \text{if } A(f) \neq 0 \\ \frac{\pi}{2} & \text{if } A(f) = 0 \end{cases} \quad (5)$$

$|F(f)|^2$ is the spectral density

$|F(f)|^2 = \frac{1}{f^\beta}$ where β is the spectral exponent, it is related to the Hurst exponent by a linear relationship $\beta = 2H + 1$

To estimate the spectral exponent, we present the spectral density versus the frequency in the log-log scale, a linear regression will provide an estimated value of β by consequence of H .

Figure 2 shows the graph of the spectral density versus the frequency in the log-log scale, the linear regression (red line)

Hurst Exponent, Fig. 1 An example of a Fractional Brownian motion realization with 1024 samples and $H = 0.60$

Hurst Exponent, Fig. 2 The spectral density of the fBm signal presented in Fig. 1 versus the frequency in the log-log scale, the red line is the linear regression

in Fig. 2 gives a slope $\beta = 2.2 \pm 0.05$ by consequence $H = 0.60 \pm 0.025$.

The Variogram

A variogram is a geostatistical method of comparing similarity of a data value to neighboring values within a field of data (Deutsch 2003). The variogram is calculated by:

$$\gamma(h) = \frac{1}{N} \sum_{i=1}^N [Z(x_i) - Z(x_{i+h})]^2 \quad (6)$$

where N is the number of neighboring data points within the specified lag distance being compared.

$Z(x_i)$: is the physical property parameter value of the initial point.

$Z(x_i + h)$: is the parameter value of the neighboring point.

The value of logarithm $\gamma(h)$ is then plotted versus logarithm the distance between the initial point and the compared points. The Hurst exponent is the slope of straight line resulting of the linear regression of this curve (Ouafeul and Aliouane 2011). The estimated Hurst exponent of the fBm signal presented in Fig. 1 is $H = 0.59 \pm 0.012$ which is very close to the actual Hurst exponent.

The Detrended Fluctuation Analysis

The method for quantifying the correlation propriety in non-stationary time series is based on the computation of a scaling exponent H by means of a modified root mean square analysis of a random walk (Peng et al. 1994).

To compute H from a time-series $x(i)$ [$i = 1, \dots, N$], like the interval tachogram, the time series is first integrated:

$$y(k) = \sum_{i=1}^k [x(i) - M] \quad (7)$$

where M is the average value of the series $x(i)$, and k ranges between 1 and N .

Next, the integrated series $y(k)$ is divided into boxes of equal length n and the least-square line fitting the data in each box, $y_n(k)$, is calculated. The integrated time series is detrended by subtracting the local trend $y_n(k)$, and the root-mean square fluctuation of the detrended series, $F(n)$, is computed as (Peng et al. 1995):

$$F(n) = \sqrt{\frac{1}{N} \sum_{i=1}^N [y(k) - y_n(k)]^2} \quad (8)$$

$F(n)$ is computed for all time-scales n .

Typically, $F(n)$ increases with n , the “box-size.” If $\log F(n)$ increases linearly with $\log n$, then the slope of the line relating $F(n)$ and n in a log-log scale gives the scaling exponent α .

where $\alpha = H + 1$

The estimated Hurst exponent of the fBm signal presented in Fig. 1 using the DFA method (see Fig. 3) is $H = 0.46 \pm 0.01$, which is different to theoretical Hurst exponent, since the DFA estimator is recommended for short time series (Ouafeul and Aliouane 2011).

The Wavelet Transform Modulus Maxima Lines

The wavelet transform modulus lines (WTMM) is a multifractal formalism introduced by Frish and Parisi (1985) revisited by the continuous wavelet transform introduced Grossmann and Morlet in 1985. The WTMM method was first introduced by Malat and Huang in 1992 and used for image processing.

The continuous wavelet transform is a decomposition of a given signal $S(t)$ into a dilated and translated wavelets $\varphi^*\left(\frac{t-b}{a}\right)$ obtained from a mother $\varphi(t)$ that must have n vanishing moments;

$$\int_{-\infty}^{+\infty} t^n \varphi(t) dt = 0, n < +\infty \quad (9)$$

$$CWT(a, b) = \int_{-\infty}^{+\infty} S(t) \varphi^*\left(\frac{t-b}{a}\right) dt \quad (10)$$

Hurst Exponent, Fig. 3 DFA estimator of the Hurst exponent of the fBm signal presented in Fig. 1, the red line is the linear fit

where $a \in \mathbb{R}^{*+}$, $b \in \mathbb{R}$

The first step of WTMM method is to calculate the continuous wavelet transform (CWT) of a given signal and the modulus of CWT, the next step is maxima of the continuous wavelet transform. Determination of local maxima is performed using the computation of the first and second derivative of the wavelet coefficients. CWT (a, b) admits a maximum at point b_0 if it satisfies the following two conditions (Ouafeul 2020):

$$\begin{aligned} \frac{\partial CWT}{\partial b} &= 0 & \text{if } b &= b_0 \\ \frac{\partial^2 CWT}{\partial b^2} &< 0 & \text{if } b &= b_0 \end{aligned} \quad (11)$$

The function of partition $Z(q, a)$ is a summation of the modulus of the CWT at local maxima b_i with a q power $\in \mathbb{R}$:

$$Z(q, a) = \sum_{b_i} |CWT(a, b)|^q \quad (12)$$

The spectrum of exponents $\tau(q)$ is related the function of partition $Z(q, a)$ by:

$$Z(q, a) = a^{\tau(q)} \quad (13)$$

So the spectrum of exponents $\tau(q)$ is obtained by a simple linear regression of $\log(Z(q, a))$ versus $\log(q)$

The spectrum of singularities is the Legendre transform of the spectrum of singularizes (Ouafeul 2020):

$$D(h) = \min_q (qh - \tau(q)) \quad (14)$$

For fractional Brownian motions signals which have monofractal character, the spectrum of exponents has a linear behavior with equation:

$$\tau(q) = qH - 1 \quad (15)$$

So the Hurst exponents are obtained by a simple linear regression of $\log(\tau(q))$ versus $\log(q)$.

The WTMM method applied to the fBm signal presented in Fig. 1 gives the following Hurst exponent $H = 0.56 \pm 0.002$.

Application to Well-Logs Data

As an example, we will calculate the Hurst exponent of the gamma ray log recorded in a vertical borehole located in the Algerian Sahara, only the depth interval [2230–2245 m] will be processed. Figure 4 shows the fluctuations of the gamma ray log versus the depth. Figure 5 shows the spectral density versus the frequency in the log-log scale, the scaling behavior of the spectral density is clear. This demonstrates the fractal behavior of the gamma ray well-log. A linear regression of logarithm the spectral density versus logarithm the frequency is done. Figure 5 shows the curve of this line (red line). The slope of this line is $\beta = 2.84 \pm 0.02$ so the Hurst exponent is equal to $H = 0.92 \pm 0.01$. The calculated Hurst exponent using the DFA method is $H = 0.60 \pm 0.04$, while the

Hurst Exponent, Fig. 4 Gamma ray log fluctuations for the depth interval [2230–2245 m]

Hurst Exponent,

Fig. 5 Spectral density versus the frequency in log-log scale of the gamma ray log presented in Fig. 4

calculated exponent using the variogram method is $H = 0.93 \pm 0.02$ and the estimated Hurst exponent using the wavelet transform modulus maxima lines is $H = 0.79 \pm 0.004$.

The DFA estimator provides an estimated Hurst exponent which is different to the spectral density, variogram, and WTMM methods, since the DFA is recommended for signals with short length (low number of samples).

A comparison between the detrended fluctuations analysis and variogram on many fBm realizations shows that for signals of high number of samples (more than 1024) variogram estimated are better than the Hurst exponents compared to the DFA. However, for signals of low number of samples we distinguish two cases (Ouafeul and Aliouane 2011):

- (a) For signals with low Hurst exponent, variogram estimates better than the Hurst exponent compared the DFA.
- (b) For signals of High Hurst exponent, DFA estimates better than Hurst exponent.

Conclusions

The Hurst exponent is an important parameter to characterize monofractal signals. It can be used to investigate the long range correlation and it is a measurement of the global regularity. Many methods have been proposed in literature to estimate the Hurst exponent. Each method estimates better the Hurst exponent for special category signals.

An example of a gamma ray well-log recorded in a vertical well located in the Algerian Sahara has been processed and

the Hurst exponent has been estimated, and there is no exact estimated value. Different methods should be compared and the signal characteristics such as length and the range of the Hurst exponent (high/low) should be taken into consideration. The Hurst exponent is very useful in the other branches of geosciences such as soil, geomagnetism, seismic, volcanology, gravity, and oceanography.

Hyperspectral Remote Sensing

Daniele Marinelli¹, Francesca Bovolo² and Lorenzo Bruzzone¹

¹Department of Information Engineering and Computer Science, University of Trento, Trento, Italy

²Center for Digital Society, Fondazione Bruno Kessler, Trento, Italy

Definition

Hyperspectral (HS) imaging is a subcategory of spectral imaging which is the process of acquiring spatially distributed and contiguous data (images) measuring the power reflected within each resolution cell (i.e., pixel) as a function of a wavelength (i.e., performing spectral measurements to analyze how light interacts with the target). While commercial digital cameras acquire images in three spectral channels corresponding to the red, green, and blue wavelengths (i.e., RGB imaging), spectral imagers such as multispectral (MS) and HS sensors perform the acquisition in multiple bands across the electromagnetic spectrum (in the order of tens or hundreds of spectral channels). MS sensors usually acquire data in a small number of spectral channels with a broad spectral resolution whereas an HS sensor acquires a much larger number of spectral bands (typically in the order of the hundreds) with a very high spectral resolution. Therefore, HS imagers perform a very dense sampling of the spectral signature, which can be seen as a fingerprint of the measured target. Due to these characteristics, HS imaging is used in a wide variety of fields including art conservation, food security, geology, and Earth observation. In Earth observation, HS images are acquired from both airborne (e.g., UAV and planes) and spaceborne platforms and are used in several applications such as precision agriculture, forestry, and urban area monitoring.

Hyperspectral Sensors

HS imagers are passive sensors using an external illumination source to illuminate the target and measure the reflected radiation as a function of the wavelength, splitting the at-sensor radiation into multiple spectral channels where

each spectral channel, or band, represents a narrow wavelength range. This can be equated to perform a spectroscopy measurement thus acquiring and sampling the spectral signature of the surface portion included in each spatial resolution cell (a pixel in the image). The reflected radiance is measured in a given wavelength range, which typically can extend from the visible to the thermal infrared.

In HS imagers, the incident radiation is split and measured for dozens or hundreds of spectral channels requiring ad hoc optical components and detectors. Few HS sensors are capable of performing full frame acquisitions (i.e., acquire the whole scene in one shot), but to this date, their use is limited mainly to astronomy. Most of the HS imagers do not acquire the whole spatial scene in one shot, as for typical RGB cameras, but perform multiple 2-D acquisitions by means of spatial or spectral scanning and aggregate them to generate the final image. This allows for the use of imagers with simpler optical components and less detectors, compared with a full frame sensor with the same spatial and spectral resolutions. In spectral scanning, each 2-D acquisition represents the whole scene at a given wavelength. The spectral scan is performed by sequentially acquiring the whole scene using tunable passband filters that filter out all the wavelengths except the range of one spectral channel. This requires no relative movements between the sensor and the target to avoid spatial misregistration among different spectral channels. In spatial scanning, the sensor, which is moving with respect to the target, acquires at each shot a portion of the scene (one or more pixels) collecting the whole spectrum all at once for each pixel imaged along a scan line. Let along-track be the direction of relative movement of the sensor with respect to the scene, and across-track be the normal direction to the along-track. To acquire the whole 2-D scene, spatial scanners exploit the relative movement between the sensor and the target to acquire in the along-track direction while they use different techniques to scan in the across-track direction. The three main technologies for such scanning are the line, whiskbroom, and pushbroom scanners. Line and whiskbroom scanners use a rotating mirror to scan in the across-track direction while acquiring one or few pixels at a time, respectively. While such systems have been used for HS imaging (e.g., the whiskbroom scanner of the AVIRIS sensor (Green et al. 1998)), pushbroom scanners have become the most common given that they do not require a rotating mirror. Indeed, pushbroom scanners scan the complete field of view in the across-track direction using a linear array of detectors with a slit aperture to acquire one line of the scene. In order to acquire the whole spectrum for each pixel, spatial scanners use an optical dispersive element (e.g., a prism or a diffraction grating) to disperse the incident broadband spectrum onto a 2-D array of detectors. Each detector measures the dispersed light in given wavelength range for a given spatial position. Therefore, for each line acquisition, a 2-D data matrix is

generated where one dimension represents the across-track (spatial dimension) whereas the other corresponds to the spectral channels (spectral dimension). Accordingly, each column (or line, depending on the sensor orientation) of detectors collects the dispersed light for one spatial pixel. The aggregated measurements of one column (or line) of detectors represent an approximation of the spectral signature of one spatial pixel. The resulting HS image can be seen as a 3-D cube defined by the triplet of coordinates (x, y, λ) , where (x, y) are the spatial coordinates, and $\lambda \in [1, B]$ is the spectral coordinate, where typically the number of spectral channels B is in the order of the hundreds. Each 2-D array of a spectral channel represents the acquired scene in one of the spectral channels (i.e., fixed λ). Figure 1 shows a simplified scheme of a pushbroom HS scanner. Spatial scanners are widely used in Earth observation since they take advantage of the motion of the platform (e.g., aircraft or satellite) with respect to the ground to perform the scanning. These scanners are used also in the opposite configuration with the sensor being fixed while the target moves (e.g., an object on a conveyor belt). This is the case of industrial applications.

Two important parameters of scanner are the spectral and spatial resolution. Let us analyze these concepts for spatial scanners mounted on moving platforms such as aircraft. However, they hold also when the scanner is fixed and the target is moving. A critical parameter of any dispersive element is the angular dispersion which corresponds to the

angular range of the incident radiation dispersion. The angular dispersion and the detector density (i.e., the number of detectors per surface unit) define the spectral resolution, which is the minimum wavelength range that can be distinguished by the sensor. Indeed, given a fixed angular dispersion, the detector density determines in how many spectral channels the dispersed light is separated. The spatial resolution is defined by the detector characteristic (width w and focal length f), the acquisition settings (acquisition rate r), the sensor-target distance, and flight parameters (altitude h with respect to the ground and platform speed s). The scanner resolution in the across-track direction is commonly referred as the instantaneous field of view (IFOV) and is defined as

$$\text{IFOV} \approx 2 \arctan\left(\frac{\omega}{2f}\right) \approx \frac{\omega}{f}. \quad (1)$$

To obtain the resolution at the target, i.e., the ground instantaneous field of view (GIFOV), the sensor-target distance must be considered:

$$\text{GIFOV} \approx 2h \tan\left(\frac{\omega}{2f}\right) \approx \frac{\omega h}{f}. \quad (2)$$

The along-track spatial resolution can be approximated as s/r . If feasible, the platform speed and/or the acquisition rate are set so that the along-track resolution is equal to the across-track to obtain square pixels. These resolutions cannot be increased indefinitely since an increase of spatial or spectral resolution leads to less energy reaching each detector. This requires to take into account the radiometric resolution of the detector: the minimum amount of energy that can be detected with an acceptable signal to noise ratio. The radiometric resolution requires a trade-off between spatial and spectral resolution. Therefore, given a specific detector, to increase spectral resolution, the spatial one has to be reduced to satisfy the detector radiometric constraint. Equation (2) shows that a way to improve the spatial resolution is to decrease the distance of the sensor from the scene which is one of the main reasons why HS sensors have been mounted mainly on airborne platform such as for the AVIRIS sensor (Green et al. 1998) rather than satellites. To guarantee both high spatial and spectral resolution on spaceborne sensors (where h is large) would require either very small detectors (thus violating the radiometric resolution constraints) or a large focal length obtaining a very large optical part of the sensor, making it unfeasible to install on a satellite. Indeed, the spatial resolution of existing and planned spaceborne HS sensors is typically in the order of the tenths of meters such as the 30 m of the recently launched (2019) PRISMA mission (Candela et al. 2016). In contrast, the spatial resolution of sensors mounted

Hyperspectral Remote Sensing, Fig. 1 Illustration of the measure concept implemented by an HS pushbroom sensor with 7 across-track pixels and 9 spectral channels. The three orange dashed lines represent the measured reflected light for the leftmost, center, and rightmost pixels of the scan line

on airborne platforms is in the order of the meters or even centimeters due to the recent new UAV-mounted sensors. However, spaceborne platforms have significant advantages which are mainly related to the repeat-pass nature of satellites that guarantees a continuous coverage in time at the global scale at no extra cost while airborne platforms require expensive ad hoc flights for each new scan.

Comparison with Multispectral Sensors

While HS sensors belong to the same family of imagers as multispectral (MS) ones, i.e., spectral imagers, there are significant differences between the two types of sensors. The distinction resides in the number of spectral channels (typically in the order of the hundreds) but most importantly in the properties of the spectral channels. Given a wavelength range, an HS imager performs an almost continuous and uniform sampling of the spectrum using uniformly spaced and narrow spectral channels across the whole range. As an example, the PRISMA sensor samples the 400–2500 nm range with 240 spectral channels having roughly the same spectral width of 10 nm. Note that some HS sensors have different spectral width for different spectral ranges such as for the future EnMAP instrument which will have a spectral sampling 6.5 nm for the visible and near infrared (VNIR) and 10 nm for the short-wave infrared (SWIR). The bands of an MS sensor are much wider (in the order of tens or hundreds of nm), have usually significantly different widths, and are non-uniformly distributed across the spectral range. Being a small number, they are positioned to sample specific portions of the spectrum. This is the case of the Sentinel-2 MultiSpectral Instrument (MSI) which has 13 spectral channels in the 400–2500 nm range with different widths and mostly distributed in the 400–1000 nm range.

Main Disturbances and Processing Challenges

HS imagers generate data cubes with a large informative content due to the fine sampling of the spectrum. While this provides significant advantages compared to MS data in terms of information content and potential applications, it comes at the cost of an increased amount of data volume and complexity that should be properly taken into account. The main challenges are related to:

- (i) The low-level preprocessing to model and possibly mitigate or remove distortions and disturbances introduced during the acquisition
- (ii) The high-level definition of a processing chain that takes into account the peculiar properties of HS data to effectively extract information

In the following, we will focus on HS imagers mounted on airborne or spaceborne platforms.

Distortions and disturbances in HS imaging are generated by both internal sources (e.g., instrument noise and optical distortions) and external sources (e.g., atmospheric effects). In addition, also geometrical disturbances (common also in MS scanners) are introduced during acquisition. These are mainly related to:

- (i) Disturbances of the platform motion (especially for UAVs)
- (ii) Acquisition geometry
- (iii) Surface morphology

These can be mitigated if a precise knowledge of position and attitude of the platform during the acquisition (acquired by an IMU/GNSS system) and of the surface morphology (i.e., Digital Terrain Model) are available.

Regarding internal sources, it is possible to distinguish between radiometric disturbances introduced by the electronics and distortions introduced by the optical components. Radiometric noise and disturbances are caused by the non-ideal behavior of the electronics and the acquisition conditions (i.e., temperature). One of the most relevant issues is the uneven responsivity of the detectors across the 2-D array leading to disturbances of the resulting HS image such as striping effects. These disturbances can be mitigated during preprocessing if the responsivity of each detector is known. Such information can be recorded and stored, before the actual data acquisition, in a responsivity matrix that can be acquired, for example, by positioning the spectrometer in an integrating sphere to provide a spatially uniform white scene of which the absolute radiance is known. Another important sensor characterization is the background noise level matrix which provides the background noise introduced by each detector. Since this noise depends on the acquisition conditions (e.g., temperature), some HS sensors are equipped to characterize the background noise level before each scan performing one or more acquisitions with closed shutter (i.e., acquisition in complete darkness) so that only noise is recorded. Such information is stored with each scan and used during the preprocessing to mitigate the effect of the noise source.

Among the distortions introduced by optical components and their misalignment, two of the most critical issues are the smile and keystone effects which are common in HS pushbroom scanners. The smile effect (spectral misregistration) is a shift of the spectral channels wavelengths as a function of the spatial position due to distortions caused by the dispersive elements or other optical components. If smile is present, a spectral line across the whole field of view is seen as a curve bent into the shape of a smile, hence the name. The keystone effect (spatial misregistration) is the

variation of the spatial position as a function of wavelength, and it is caused by a wavelength-dependent magnification of the radiation onto the detector array. This makes the same object to appear in different positions of the image depending on the wavelength. Such distortions can significantly affect the spectral/spatial information in HS data leading to a decrease of performance in the processing chain. Indeed, keystone can strongly change the spectral signatures especially on the boundaries between different materials (i.e., in areas with strong spatial variability) mixing spectra in an unrealistic way. These effects can be corrected, or at least mitigated, during preprocessing by characterizing them across the whole detector matrix. Such characterization can be obtained by directly analyzing the HS data cube as in Neville et al. (2004) where the spatial correlation of spectral channels is used to model the keystone. Alternatively, precise measurements can be conducted in a controlled environment to produce smile and keystone characterization matrices to be used in the preprocessing to reduce the impact of these distortions. This can be done using an integrating sphere to illuminate the imager with narrow band (for smile) or broadband (for keystone) light sources to measure the magnitude of the distortions across the whole detector matrix.

Regarding effects of the atmosphere, depending on the acquisition conditions such as altitude, water vapor column, or the presence of aerosols, the radiance measured at the sensor (i.e., at-sensor radiance) can be altered with respect to the at-surface radiance, leading to measurements where the spectral signatures are noticeably different with respect to the actual reflectance. Algorithms that take as input several parameters such as the time and location of the acquisition can be used to model and remove atmospheric disturbances. They include the ATmospheric REMoval (ATREM) (Gao and Davis 1997) and the Fast Line-of-sight Atmospheric Analysis of Spectral Hypercubes (FLAASH) (Cooley et al. 2002) algorithms.

Moving to the processing, one of the challenges is related to the high number of spectral channels that results in a high dimensional feature space where data should be analyzed. The analysis of data in high dimensional spaces is affected by several problems that are grouped under the name curse of dimensionality. Indeed, since the number of samples (pixels in the case of HS images) is finite, as the number of features (i.e., spectral channels) increases, the volume of the feature space increases quickly with the data becoming more and more sparse. This leads to a decrease of effectiveness of techniques developed for low dimensional spaces such as for distance metrics where in high dimensional spaces, the distances between different pairs of coordinates tend to become all similar (Bellman 2015). Another problem of high dimensional spaces like those defined by HS data is related to supervised data analysis techniques related to the Hughes phenomenon (Melgani and Bruzzone 2004). This

phenomenon describes the unintuitive decrease of accuracy as the number of features given as input to a classifier goes above a certain value for a fixed number of training samples. It is caused by the small ratio between the number of training samples and the number of features that prevents a reliable modelling of the statistical properties of the data. The high dimensionality of HS data introduces also technical challenges related to the data volume given by the large number of values to be stored for each pixel typically with high radiometric resolutions (i.e., large number of bits representing pixels value) that may lead to problems related to both storage, computational load, and memory needs.

Main Methodologies and Applications in Earth Observation

HS images can be used in a wide variety of applications where a detailed knowledge of the spectral properties of a scene or object is required. Some of them are:

- (i) Earth observation
- (ii) Food security
- (iii) Cultural heritage preservation
- (iv) Civil engineering
- (v) Medical imaging

In Earth observation, HS data are used in multiple applications including agriculture, forestry, mining, water, and cryosphere monitoring. HS data are analyzed by different methodological approaches having different objectives, among which the most common are classification (Ghamisi et al. 2017), target detection (Nasrabadi 2014), spectral unmixing (Bioucas-Dias et al. 2012), and in recent years, change detection (Liu et al. 2019). Classification exploits the detailed spectral information of HS data to discriminate classes showing very similar yet different spectral signatures that result inseparable at the spectral resolution of MS data. Therefore, HS images allows for the generation of detailed classification maps with a wide variety of classes. Classification of HS data is used in different applications and environments including:

- (i) Urban mapping
- (ii) Mineral mapping
- (iii) Agriculture for the automatic identification of crops
- (iv) Forestry for the generation of tree species maps

If more images are available for the same area, it is possible to exploit HS data to monitor the dynamics of the land cover at a fine spectral resolution. Indeed, while methods for change detection in MS data focuses mainly on abrupt changes that correspond to a strong intensity variation over a large range of

the spectrum (e.g., transition from vegetation to concrete), using HS multitemporal data is possible to detect changes associated to variations that affect only limited portions of the spectrum and are invisible to MS sensors. Similar considerations hold in the case of multiple change detection (i.e., identification and discrimination among change types) where HS data allows us to separate changes that differ only in limited ranges of wavelengths. Change detection methods for HS data can be used for several applications such as to monitor open-pit mines, track the crops evolution in agricultural areas, and forestry monitoring.

Another set of methodologies for HS data processing is spectral unmixing. Since especially for spaceborne data the spatial resolution is limited, it is common that pixels contain more than one type of material resulting in a spectrum which is a mix of the spectra of the different materials. The aim of unmixing techniques is to automatically separate the mixed spectra to identify the materials (i.e., endmembers) and their abundance in the pixel. A critical aspect of unmixing is the need of formulating a model for the mixture. This can be linear or nonlinear with the first being the most common due to the easier implementation. The linear model describes the mixture as a weighted sum of the individual spectra where the weights correspond to the abundance value. In this case, the unmixing can be performed using, for example, least square methods given that the spectra of the endmembers are known. These can be done by extracting them from the pure pixels in the image or using existing spectral libraries.

It is worth noting that while these are the most common methodologies and applications, Earth observation HS data have several other uses. In the case of agriculture, forestry, or vegetation monitoring, HS data are used to monitor specific aspects. They include the monitoring of several plants health factors such as water stress and the diffusion of diseases. HS data are also used for water quality analysis generating different products such as the concentration of chlorophyll and total suspended matter. Another application field is related to the monitoring of glaciers and snow both in terms of classification and the extraction of specific parameters such snow grain size, wetness, and surface contamination. Such parameters provide valuable information as they can be used to study the status of glacier and predict the melting rate.

Summary and Conclusions

Hyperspectral images provide a very detailed representation of the spectral reflectance of the target surface. Such data have been used in several applications such as land cover maps generation and agricultural monitoring and methodologies including classification and change detection where the dense sampling of the spectrum can be used to separate classes or changes associated to very similar, yet semantically

different, spectral signatures which are undistinguishable in MS images. Indeed, compared to MS, sensors which sample spectrum at few broad bands, HS imagers perform a dense sampling of the spectrum across the whole spectral range of interest. However, the analysis of HS images requires to address several challenges related both to disturbances and distortion introduced during the acquisition and the processing of high dimensional data.

While to this date HS images are still relatively less used than MS images, this will significantly change in the next years due to the current new sensors, future HS spaceborne missions, and the new generation of compact HS imagers designed specifically for UAV systems. Accordingly, HS data will become more and more available and thus their use in operational scenarios will significantly increase.

Hypothesis Testing

Synonyms

Significance testing; Statistical hypothesis testing; Statistical test

Definition

A hypothesis test comprises a procedure aimed to prove, or not, a statistical statement or conjecture.

A statistical hypothesis $\mathcal{H}$ comprises a statement or conjecture made about one or several statistical elements like random variables, populations, distributions, or even parameters. Therefore, a hypothesis test stands for a procedure performed to decide whether $\mathcal{H}$ should be rejected or not.

Generically, let us suppose a data space $\mathcal{X}$ where it is observed a sample $\{X_i : i = 1, \dots, n\}$ whose elements are realizations of a random variable $\mathbf{X}$. Such sample is observed aiming to infer about particular propriety stated by $\mathcal{H}$. A critical region $C_\tau \subset \mathcal{X}$ represents extreme situations stated according to a statistic of test τ . Whether verified that $\{X_1, \dots, X_n\}$ comes from the critical region, the hypothesis $\mathcal{H}$ is rejected.

Usually, $\mathcal{H}$ is unfolded into a null ($\mathcal{H}_0$) and an alternative ($\mathcal{H}_1$) hypothesis. While $\mathcal{H}_0$ states that there is no difference between the statistical elements under comparison (i.e., the difference is null), the hypothesis $\mathcal{H}_1$ contradicts the previous one. In the light of these discussions, if $\mathcal{H}_0$ is assumed as false, then $\mathcal{H}_1$ becomes valid and $\mathcal{H}_0$ is rejected; in turn, if $\mathcal{H}_0$ is considered true, then $\mathcal{H}_1$ is false and $\mathcal{H}_0$ should not be rejected. Still, when $\mathcal{H}_1$ only establishes that there is a

difference between the compared elements, the hypothesis test is bilateral (or two-sided). On the other hand, when the difference has a direction (i.e., positive or negative), the hypothesis test is unilateral (or one-sided).

Regarding the process to decide about the rejection of $\mathcal{H}_0$, it may occur a type I error, when it rejects $\mathcal{H}_0$ although it is a valid hypothesis; or a type II error, when it does not reject $\mathcal{H}_0$ although it is not valid. In other words, a type I error (also called false positive error) means that the conclusions point to reject $\mathcal{H}_0$, but in fact, such rejection occurred by chance. The type II error (also called false negative error) implies no statistical difference, although such difference is a reality.

The occurrence probability of type I and type II errors are usually denoted by α and β , respectively. Furthermore, α is called as the “significance of the test” and the probability $(1 - \beta)$ is the “power of the test.” β is computed through a theoretical probability distribution that expresses the values from τ that leads to the rejection of $\mathcal{H}_0$.

Without loss of generalization, suppose one tests the hypothesis that a parameter θ of a population differs from θ_0 obtained through an observed sample. A hypothesis test may be structured according to the following steps (Mood et al. 1974):

- (i) Define the hypothesis:

$$\mathcal{H}_0 : \theta = \theta_0$$

$$\mathcal{H}_1 : \theta \neq \theta_0 \text{ if bilateral; } \theta \leq \theta_0 \text{ (if unilateral)}$$

- (ii) Identify the appropriate statistic of test τ .
- (iii) Specify the significance of test α and define the critical region C_τ to reject $\mathcal{H}_0$.
- (iv) Compute τ and decide whether $\mathcal{H}_0$ is rejected.

Additionally, after selecting τ and computing the value $\hat{\tau}$ with basis on $\{X_1, \dots, X_n\}$, it is also possible to determine the probability p of occurring a value equal or more extreme than $\hat{\tau}$. Such probability is called p -value and leads to the rejection of $\mathcal{H}_0$ when $p < \alpha$.

Brief Overview

One of the first statistical inference techniques, the so-called “parametric” tests, is usually based on assumptions regarding the distribution of the population. Posterior, “non-parametric” techniques rise as an alternative approach that is independent of previous suppositions. Regardless of its parametric or non-parametric basis, the hypothesis tests in the literature may be categorized as, but not limited to, tests for a single sample; two paired or independent samples; several paired or independent samples; correlation; concordance; and time-series.

While tests for a single sample focus on checking if a set of observations is adherent to a specific distribution or has an expected parameter, the tests for two or several samples compare if such samples are, or not, similar. The denomination “paired” implies that the samples are element-wise compared. “Independent” means that the comparisons do not consider the order of the elements or suppose a relation among them. Correlation and concordance tests check the significance of correlation values computed through two or multiple variables. Lastly, tests for time series allow proving the existence of trends in the data over time.

There are several hypothesis tests in the literature, making it unfeasible to cover this topic herein. Therefore, the following discussions embrace just some most popular tests. More details are given for tests of a single sample as well as for two samples.

Tests for a Single Sample

The T -test is a parametric test to check if a sample differs from the population's mean value. This test is conditioned to the suppositions that the population follows a Gaussian distribution; the sample is small ($n \leq 30$); the observations were randomly and independently drawn; and the population standard deviation is unknown. The T -test statistic is expressed by:

$$t = \frac{\bar{X} - \mu}{s/\sqrt{n}} \quad (1)$$

where μ and $\bar{X}$ stands for the mean value from the population and the estimated mean from the sample, respectively; s and n represent the standard deviation and the number of observations from the sample, respectively. Once it follows a Student's T distribution with $(n - 1)$ freedom degrees, the rejection of $\mathcal{H}_0$ occurs when t lies the critical region defined according to the adopted significance α . Tabulated values or computed through the integral of Student's T distribution function may be employed to obtain the critical region.

When the population standard deviation σ is known and the sample is not small ($n > 30$), the Z -test is the alternative to T -test. The statistic z follows a standard Gaussian distribution and is defined replacing s by σ at Eq. 1.

Tests for Two Samples

Given the samples $X = \{X_1, \dots, X_n\}$ and $Y = \{Y_1, \dots, Y_m\}$, a variant of T -test allows comparing the mean values from two samples. The statistic t for this case is defined

as:

$$t = \frac{\bar{X} - \bar{Y}}{\sqrt{s_X^2/n + s_Y^2/m}} \quad (2)$$

where $\bar{X}, \bar{Y}$, s_X , and s_Y are the means and standard deviations computed through the samples X and Y , which are composed by n and m observations, respectively. The same suppositions made for the single sample version still kept.

The statistic t follows a Student's T distribution with $(n + m - 2)$ freedom degrees. The critical region definition and rejection of $\mathcal{H}_0$ are similar to its single sample version.

In analogy, knowing the standard deviations σ_X and σ_Y regarding the populations where X and Y are extracted, the comparison of its mean values is carried through the Z -test for two samples. Again, the statistic of this test follows a standard Gaussian distribution and is defined replacing s_X and s_Y by σ_X and σ_Y in Eq. 2.

When the focus is to check the similarity between the variances of two populations, with supposed Gaussian distributions, the F -test may be applied. Its statistic of test f , defined in Eq. 3, follows a Snedecor F -distribution with parameters $(n - 1)$ and $(m - 1)$ freedom degrees.

$$f = \frac{(m - 1) \sum_{i=1}^n (X_i - \bar{X})^2}{(n - 1) \sum_{j=1}^m (Y_j - \bar{Y})^2} \quad (3)$$

A non-parametric alternative to the T -test is given by the U Mann-Whitney test. In this case, supposing that the samples X and Y has at least 20 observations, the u statistic expresses the Mann-Whitney's test:

$$u = \frac{U - nm/2}{\sqrt{(nm(n + m + 1))/12}} \quad (4)$$

with $U = \min \{U_X, U_Y\}$ where $U_X = nm + \frac{n(n+1)}{2} - R_X$, $U_Y = nm + \frac{m(m+1)}{2} - R_Y$; R_X is obtained by the sum of ranks assigned to the observations in X after a joint regarding both observations from X and Y ; R_Y is computed in analogy to R_X . If the samples does not attain the minimum required size, distinct procedures, as discussed in Siegel and Castellan (1988) and Sheskin (2011), should be adopted. The statistic u follows a standard Gaussian distribution, and then such distribution rules the critical region definition and $\mathcal{H}_0$ rejection.

In the case of paired comparison, the Wilcoxon test is a non-parametric procedure that can be employed to determine whether or not two samples X and Y represent the same population. When the analysis involves small samples, this test embraces: (i) calculate the difference d_i relative to the

scores of the pair (X_i, Y_i) ; (ii) assign a rank to each d_i regardless of its sign; (iii) include the sign to the ranks; and (iv) calculate the statistic r that corresponds to the sum of the ranks of the same sign. Finally, the probability of occurrence of r is obtained through tabulated distribution (Siegel and Castellan 1988; Sheskin 2011). However, when the number of pairs is greater than 25, the statistic of test w , which comes from the sum of the ranks follows a standard Gaussian distribution, is expressed by:

$$w = \frac{r - (n(n+1))/4}{\sqrt{(n(n+1)(2n+1))/24}} \quad (5)$$

where n is the number of observations in both samples X and Y . Once again, the decision to reject $\mathcal{H}_0$ is still in the same mood as previous discussions.

Tests for Several Samples, Correlation, Concordance, and Time Series

Hypothesis tests for comparisons involving several samples are not performed essentially by combining tests for two samples applied to each pair of samples. On the assumption of normal distribution of k samples, whose variances are equal, the analysis of variance (ANOVA) allows comparing the means of these samples. In this test, $\mathcal{H}_0$ is characterized as a simultaneous equivalence among the means of all samples (i.e., $\mathcal{H}_0 : \mu_1 = \mu_2 = \dots = \mu_k$), and $\mathcal{H}_1$ establishes that there is difference at least between a pair of samples. This technique has different versions and may be applied on paired and independent samples. The statistic of the test resulting from the ANOVA follows Snedecor's F-distribution. For this situation, when the data does not respect the assumptions required by the parametric approaches, the Friedmann and Kruskal-Wallis tests are the alternatives to deal with paired and independent samples, respectively.

Correlation coefficients are applied to measure the relationship between variables to explain how a variable behaves in a scenario where the other changes. The Pearson and Spearman coefficients are, respectively, the parametric (it assumes that a bivariate Gaussian distribution expresses a joint distribution of the variables) and non-parametric ways of measuring the correlation between variables. These correlation measures range in $[-1, +1]$, where the lower and upper bounds indicate perfect inverse and direct correlations, respectively. When these measures approach zero, it implies that there is no correlation between the variables. In addition to calculating and interpreting the correlation values, a hypothesis test can be applied to verify that such value is significant to the null coefficient (i.e., no correlation).

Correlation coefficients involving more than two variables can be computed using Kendall's coefficient.

Agreement coefficients extracted from contingency tables (confusion matrices) that express the relation between expected and observed quantities according to different classes are also subject to hypothesis tests. Specifically, values of coefficients such as kappa (κ) and tau (τ) from different confusion matrices may have their significance verified through statistic of tests in the form $\frac{c_1 - c_2}{\sqrt{\sigma_1^2 + \sigma_2^2}}$ where c_1 and c_2 represent the agreement coefficients (of common type) and σ_1^2 and σ_2^2 of the variances associated with the respective coefficients. The presented statistic follows standard Gaussian distribution.

Finally, regarding the analysis of time series, identifying increasing or decreasing trends is of great importance. In this context, the Mann-Kendall test allows this verification where the $\mathcal{H}_0$ and $\mathcal{H}_1$ hypotheses imply the absence and existence of a trend in the observed period, respectively.

Applications in Geosciences

A hypothesis test is an essential tool in data analysis processes. Regarding the geosciences, several studies employ this concept.

In Luo and Yang (2017), hypothesis tests are used to verify the effectiveness of a sensor network developed to detect the concentration of water pollution. In this case, the T -test is applied to identify deviations from expected behavior and then reveal the presence of the pollutant source. In Eberhard et al. (2012), the Wilcoxon test is used to evaluate the accuracy of earthquake forecasting models. Similarly, Jena et al. (2015) employs the Z -test, among others, to evaluate the precipitation and climate change models. Finally, Nascimento et al. (2019) develop a new hypothesis test to perform temporal change detection in the Earth's surface using polarimetric images obtained by remote sensing.

Summary

A hypothesis test is a fundamental statistical procedure designed to check statistical elements like random variables, populations, distributions, or parameters that behave according to a statistical hypothesis.

Hypsometry

Sebastiano Trevisani¹ and Lorenzo Marchi²

¹Università Iuav di Venezia, Venice, Italy

²Consiglio Nazionale delle Ricerche – Istituto di Ricerca per la Protezione Idrogeologica, Padova, Italy

Definition

In very general terms, hypsometry is the measurement of land elevation. In geomorphology, hypsometry refers to the analysis of the cumulative distribution of the elevation, absolute or relative, in a given region. The distribution of elevation is a basic topographic feature of a territory, and its representation is useful for interpreting and characterizing geomorphic processes. Hypsometry can be computed in spatial domains of any shape and extent, including the whole earth surface; however, often the studies of hypsometry focus on drainage basins.

Hypsometric Parameters

Hypsometric curves, which represent the fraction of area above a given elevation, are a widely adopted tool for the graphical representation of hypsometry. The hypsometric curve is the cumulative distribution of elevation in a defined spatial domain of analysis (Hypsometry, Fig. 1). Hypsometric curves are often presented in nondimensional form

(Hypsometry, Fig. 2), which enables the comparison between different regions or drainage basins. Nondimensional hypsometric curves are plots of the relative height (h/H) versus the relative area (a/A) of the region under investigation (Hypsometry, Fig. 1). The relative height is the ratio of the height above the lowest point in the basin at a given contour to the total relief ($H=H_{max}-H_{min}$), and the relative area is the ratio of horizontal cross-sectional area at that elevation to the total area (i.e., the frequency of values above a given threshold of elevation h).

Hypsometry requires the assessment of the areas at different elevation belts, which was done in the past through manual measurements on topographic maps with contour lines, and is now easily implemented through the analysis of digital terrain models (DTMs) or, more in general, digital elevation models (DEMs).

From the hypsometric curve, multiple parameters describing the statistical distribution of elevation can be derived. One of the most popular parameter is the hypsometric integral (HI), which corresponds to the area below the nondimensional hypsometric curve, a numerical index introduced by Strahler (1952) to summarize the hypsometry of fluvial basins. From the geometrical point of view, the hypsometric integral is the ratio between the volume contained between the land surface and the base plane (Hypsometry, Fig. 1b) and the volume obtained extruding the base plane for the basin relief (Hypsometry, Fig. 1c).

A simple equation (Eq. 1) proposed by Pike and Wilson (1971) permits the computation of the hypsometric integral (HI) using the mean (H_m), minimum (H_{min}), and maximum (H_{max}) elevation in the studied area:

$$HI = \frac{H_m - H_{min}}{H_{max} - H_{min}} \quad (1)$$

The hypsometric curves and integrals are robust against different estimation methods (Singh et al. 2008). In case of derivation from a DTM, HI shows low sensitivity to variations in DTM resolution (Hurtrez et al. 1999). These features enable the comparison of hypsometric parameters computed with different methods and using topographic data of different resolutions. However, a relevant limitation of the hypsometric integral is that different hypsometric curves, which imply different distribution of areas with elevation, could have similar hypsometric integrals.

In earth sciences and ecological studies, multiple indices derived from hypsometry are considered, including statistical moments of the distribution of elevation and the possibility to consider the probability density distribution. In this regard, the modeling of the experimental hypsometric curve with a theoretical function (Strahler 1952) facilitates the derivation of descriptive indices. For example, third degree polynomial

Hypsometry, Fig. 1 (a) sketch with the main geometric elements of hypsometry for a drainage basin (modified from Strahler 1952); (b and c) representative volumes in hypsometric integral calculation

Hypsometry, Fig. 2 Nondimensional hypsometric curves for three stages of drainage basin evolution (modified from Strahler 1952)

curves (Eq. 2) have been widely applied to fit the hypsometric curves in a quite wide range of morphological settings.

$$h/H = c_1 + c_2 \cdot a/A + c_3 \cdot (a/A)^2 + c_4 \cdot (a/A)^3 \quad (2)$$

where c_1 , c_2 , c_3 , and c_4 are coefficients determined by curve fitting. However, in presence of complex hypsometric curves, related, for example, to lithological and geomechanical heterogeneities in the basin, as in the monadnock phase, these polynomials are not sufficiently flexible (Vanderwaal and Ssegane 2013).

Relevance in Geomorphology

In his pioneering studies on hypsometry, Strahler (1952, 1957), considering also the work of Langbein et al. (1947), related the shape of the hypsometric curves and the values of hypsometric integral to the different stages of evolution of drainage basins (Hypsometry, Fig. 2). A young stage features high hypsometric integrals and is characterized by inequilibrium conditions that lead to a mature equilibrium stage. The monadnock phase with very low hypsometric integral, when it does occur, can be followed by a return to equilibrium conditions after the removal of isolated elevated areas of resistant rock.

Several studies (e.g., Willgoose and Hancock 1998; Hurtrez et al. 1999; Korup et al. 2005) have provided evidence of the scale dependency of hypsometric parameters of drainage basins. The transition from diffusive to fluvial dominance (Willgoose and Hancock 1998), which affects the relative importance of river processes versus hillslopes processes (Hurtrez et al. 1999), determines the dependence of hypsometry on basin scale. The shape of the hypsometric curves (e.g., Lifton and Chase 1992; Pérez-Peña et al. 2009; Marchi et al. 2015) is directly related to multiple geomorphic processes and factors, such as geostructural setting, lithological heterogeneity, climatic factors, and biotic processes which control the morphological evolution of a basin.

Given the relationships between hypsometric characteristics and geomorphic processes and factors, it is not surprising the ample literature related to the exploitation of hypsometric-based indices in multiple research contexts, not limited to the analysis of drainage basins (e.g., morphology of glaciers, planetary morphology, etc.). Moreover, hypsometry-based indices are also considered in geomorphometry as input

parameters for geocomputational approaches based on supervised (e.g., landslide susceptibility models) and/or unsupervised learning (e.g., landscape classification based on geomorphometric features).

Application in Hydrology

In hydrology, hypsometry helps computing the spatial average precipitation in regions where the orographic effects are important. In the traditional approach, the combined use of a relationship linking precipitation and elevation and the hypsometric curve permits assessing the precipitation at different elevation belts and the mean average precipitation in the studied area (Dingman 2002). Like in other sectors of quantitative terrain analysis, also in the assessment of mean areal precipitation, the use of gridded elevation data permits taking into account the effect of elevation without using graphical tools such as the hypsometric curve.

Conclusions

Hypsometry describes the statistical distribution of elevations in a defined spatial domain of analysis, often represented by a drainage basin, through parameters that provide a spatial-statistical representation of a landscape. Hypsometry can thus be considered a precursor of modern geomorphometry.

Hypsometry has found many applications in geomorphology: it was historically considered as an indicator of basins and landforms evolution and was then related to the geomorphic processes and their controlling factors.

Care should be paid when using hypsometric curves and derived parameters, such as the hypsometric integral, for comparative purposes. The dependency of hypsometry on multiple geomorphic processes and factors, and, in some conditions, on spatial scale should be always taken into account.

Imputation

Javier Palarea-Albaladejo
Biomathematics and Statistics Scotland, Edinburgh, UK

Definition

In data analysis and statistical modelling, imputation refers to a procedure by which missing or defective entries in a data set are replaced by plausible estimates to generate a complete data set that is usable for further processing.

Missing Data and Nondetects in Geoscientific Studies

Modern datasets generated in the geosciences ordinarily contain collections of variables referring to varied characteristics of the medium under study. The observed data are a realization of the underlying physical and chemical processes being investigated and multivariate statistical methods are well suited for their analysis and interpretation. Thus, along with the specialized methods of geostatistics, which are mostly focused on modelling spatiotemporal phenomena, multivariate techniques for data reduction, classification, and prediction are part of the basic quantitative toolbox of the geoscientist. Regardless of how cautiously a researcher designs and executes a study, one of the most prevalent problems in empirical work relates to the presence of missing values in multivariate data sets. Missing data in general can be due to many reasons, e.g., circumstances affecting data collection, failures of the instruments, or data handling issues. These are commonly indicated in a data matrix by empty cells or using a special code or character. A prevalent type of missing data in the geosciences refers to left-censored data. For example, in spatial exploratory studies, there are frequently geographic locations where indicators of the presence

of an element of interest are found, but its precise quantities cannot be determined. This commonly corresponds to trace element concentrations falling below the limit of detection of the measuring instrument and is a form of left-censored data: the actual value is unknown, but we do know that it must be somewhere in the lower tail of the data distribution below the detection limit. Thus, they are often called less-thans or non-detects. A detection limit (DL) is considered a threshold below which measured values cannot be distinguished from a blank signal or background noise, at a specified level of confidence.

Once it has been deemed impossible to recover the actual values, the practical problem is how to deal with missing data, nondetects, or often both simultaneously, to be able to carry on with data analysis and modelling. Statistical analysis based on only the available data, or after a naïve substitution of the unobserved values, can introduce important bias and achieve reduced statistical power, particularly as the number of cases increases. These solutions are unfortunately common default options in statistical software packages.

Missingness Mechanisms

Frameworks for missingness mechanisms have been developed that can assist in determining the approach to deal with missing data. Understanding the occurrence of missing elements in a data matrix $\mathbf{X} = (\mathbf{X}_{obs}, \mathbf{X}_{mis})$ as a probabilistic phenomenon, with $\mathbf{X}_{obs}$ and $\mathbf{X}_{mis}$ referring to the observed and missing partitions, respectively; we can define a random missingness matrix $\mathbf{M}$ with elements 0 or 1 corresponding to observed or missing values in $\mathbf{X}$ respectively. Depending on the conditional distribution of $\mathbf{M}$ given $\mathbf{X}$, and a set of unknown parameters ξ , the missingness mechanisms are generally classified as:

- Missing completely at random (MCAR), when the probability of missingness is the same for all elements of the data

matrix, i.e., $P[\mathbf{M} | \mathbf{X}_{obs}, \mathbf{X}_{mis}; \xi] = P[\mathbf{M}; \xi]$. This is the simplest case, implying that missing values are a random sample of the data matrix. Basic approaches like data analysis using only the observed data can be sensible in this setting, however this is generally unrealistic.

- Missing at random (MAR), when the probability a value is missing depends only on the available information, i.e., $P[\mathbf{M} | \mathbf{X}_{obs}, \mathbf{X}_{mis}; \xi] = P[\mathbf{M} | \mathbf{X}_{obs}; \xi]$. This is the situation most commonly assumed in practice. The missing part can be ignored as long as the variables that affect the probability of a missing value are accounted for. Note, however, that if $\mathbf{M}$ depended on other variables that are not explicitly included in $\mathbf{X}_{obs}$, then MAR would no longer be satisfied.
- Missing not at random (MNAR), when the probability a value is missing depends on the value itself and hence both $\mathbf{X}_{obs}$ and $\mathbf{X}_{mis}$ are involved. This is the most complicated situation and implies a systematic difference between the observed and missing data. The case of nondetects as discussed above falls into this category.

Given its practical relevance, the treatment of missing data is an active statistical research area with ramifications throughout varied applied disciplines (Little and Rubin 2002; Molenberghs et al. 2014). Approaches like complete-case analysis (list-wise deletion) or available-case analysis (pair-wise deletion) simplify the problem by discarding data. The first leaves out all samples including any missing values. The second intends to maximize the use of the information available in each case. Thus, e.g., the calculation of means can be based on different samples depending on the missingness pattern of each variable and, analogously, correlations use data simultaneously available for each particular pair of variables. Note that the latter can lead to the technical issue of non-definite positiveness of correlation matrices, preventing the use of most multivariate techniques. As stressed above, these strategies must be used with great caution, particularly when missing data are not MCAR and there are meaningful associations between variables. Nonetheless, it is not feasible to define universal rules of thumb about when to use these methods or not, or actually any others. A fundamental consideration is of course the rate of missing data, but there are also important factors that are context specific. Hence, some testing and exploration blended with expert knowledge would better assist in making informed decisions in practice.

More sophisticated methods that commonly assume a MAR mechanism include different forms of regression modelling, likelihood-based estimation methods, Bayesian data augmentation, and single and multiple imputation procedures. For the MNAR case of nondetects, a popular approach among practitioners in the earth and environmental sciences is simply substituting them by a fraction of the detection limit, typically $DL/2$, or simply using DL itself.

Advantages of this simple substitution are simplicity and the fact that no model assumptions are made. However, different studies have shown the distortion and undesirable consequences that such practice can have and advocate for methods that exploit the statistical properties of the data. Specialized maximum likelihood, robust, and nonparametric methods have been introduced for the unbiased estimation of common univariate statistics (means, standard deviations, quantiles, and so on) from left-censored data (Helsel 2012). However, these are not well suited for complex missingness patterns typical of multivariate data sets, possibly in high dimensions, which often involve varied interrelations between variables, for example spatial or temporal dependencies. Thus, prediction to recover the regional structure of an analyte or mineral resource and estimation of the overall spatial variability are common tasks in spatial modelling. These may benefit from exploiting the spatial correlation to deal with any censored data (Schelin and Sjöstedt-de Luna 2014).

Multivariate Data Imputation

Data imputation provides an intuitive and powerful tool for the analysis of multivariate data with complex missing data patterns. The basic idea is straightforward: replacing missing values across variables by plausible values, ideally by statistically exploiting the observed data and the associations between variables, using different approaches depending on the nature of the data (van Buuren 2018; Schafer 1997). The result is a completed version of the data set that allows to carry on with the subsequent data analysis and modelling. Note that imputation can be also useful to deal with other forms of irregular data such as outliers, particularly when these are regarded as erroneous or inaccurate measurements. There exists a wide range of imputation methods of varied levels of complexity. The actual impact of any procedure on the results will depend on the characteristics of the data set and the focus of the subsequent analysis. We refer the reader to the general references provided above for an overview. One of the simplest methods is mean imputation, i.e., replacing missing values in a variable by the mean of the observed values. Note that this will tend to underestimate standard deviations and distort the correlations between variables. Model-based imputation will be generally preferred for moderate to high fractions of missing data in regular multivariate data sets, even when the imputation model only weakly agrees with the model assumed for the complete data (Schafer 1997). Unlike single imputation, multiple imputation is meant to create several versions of the imputed data set and combine estimates from them. This principally aims to incorporate the extra uncertainty derived from the own imputation process to the estimation of standard errors and, hence, to, e.g., the determination of rejection regions in statistical hypothesis

testing. Methods within the sphere of machine learning such as random forests or k-nearest neighbors (KNN) algorithms have been also formulated to serve as imputation devices. Other imputation methods particularly relevant in computationally intensive high-dimensional contexts, e.g., in high-throughput experiments, rely on low-rank matrix completion. Specialized computer routines can nowadays be found in the most popular statistical computing platforms. Within the open-source arena, we refer the reader to The Comprehensive R Archive Network (CRAN) Task View on missing data (<https://cran.r-project.org/web/views/MissingData.html>), which keeps a detailed account of related packages available on the R statistical computing environment.

The Case of Compositional Data

Compositional data (CoDa) are observations referring to fractions or parts of a whole, often represented in units such as proportions, ppm, weight %, mg/kg, and similar.

Compositional data are ubiquitous in different areas of the geosciences, including geochemistry, soil science, mineralogy, sedimentology, among others (Buccianti et al. 2006; Tolosana-Delgado et al. 2019). Compositions are defined on a sample space equipped with a special geometry that departs from the ordinary real space assumed by most statistical methods. Hence, statistical analysis and modelling of CoDa present some challenges and particularities that are not well addressed by conventional methods, which can lead to misleading results and interpretations. The mainstream approach to CoDa analysis involves focusing on (log-)ratios between the parts of the composition. These log-ratios carry the relevant relative information and crucially do not depend on an arbitrary scale of measurement.

Note that zero values do not fit into the above conceptualization, since they are incompatible with the ratio and logarithm operations. However, they commonly occur in experimental studies involving compositions. Hence, this has been a particularly important issue in practical CoDa analysis. Zero parts in our context often concur with the

Imputation, Fig. 1 Patterns of missingness generated by simulation in illustrative geochemical data set and relative frequencies of cases

concept of nondetects as described above, i.e., small values that have been rounded off or have fallen below a limit of detection and then registered as zeros. The problem is more complex here than in standard multivariate analysis due to the fact that a single unobserved part renders the whole composition undefined. A basic property of any method to deal with zeros, nondetects, or missing data in general within this context, is that they should preserve the relative variation structure of the data. A number of specialized imputation methods have been developed in CoDa analysis following different methodological flavors. The R package *zCompositions* (Palarea-Albaladejo and Martín-Fernández 2015) provides an integrated framework for compositional data imputation (applicable to zeros, nondetects, missing data, or combinations of them) following the principles of the log-ratio approach. This includes a consistent treatment of closed and non-closed compositions, unique or varying detection limits, parametric and nonparametric imputation, single and multiple imputation, maximum likelihood and robust estimation, and other related tools.

For illustration, we used 66 complete samples of a 14-part geochemical composition (in $\mu\text{g/g}$) from La Paloma stream (Venezuela) including the elements K, Ti, P, Ce, Ba, Li, Rb, V, Sr, Cr, B, Y, La, and Cu (the entire data set is available in *zCompositions*; the elements have been sorted here by decreasing mean relative abundance). The first five were considered major elements, whereas the remaining nine were assumed to be minor elements. We simulated around 15% of missing values in each of a random selection of 60% of the major elements (MCAR; 3.25% missing overall) and around 10% of nondetects in each of a random selection of 70% of the minor elements (using their 10% quantiles as DLs; 4% nondetects overall). This generated an artificial data set including 30 complete samples (45.45%); along with 18 (27.27%), 11 (16.67%), and 7 (10.61%) samples having respectively either missing, nondetect, or both types simultaneously. Figure 1 summarizes the patterns of missingness in the data using the *zPatterns* function in *zCompositions* (combining missing and nondetects and sorting patterns by decreasing frequency). The bars on the sides indicate the percentage cases, either by element (columns) or samples per pattern (rows).

Imputation was conducted using the *lrEMplus* function in *zCompositions* (missing and nondetect values were coded as NA and 0, respectively, for this), with the 10% quantiles used as vector of DLs for the nondetects. This function implements an iterative model-based regression-type imputation method (more details and references can be found in the documentation accompanying the package). Basic compositional summary statistics of central tendency and variability were computed from the originally complete data and the imputed data to briefly assess the results. In particular, Table 1 shows

Imputation, Table 1 Compositional summary statistics from complete and imputed data sets: closed geometric mean (in percent units), total variance, and individual contributions to total variance (raw and percent values)

	Complete data		Imputed data

the closed geometric mean (CGM; a.k.a. compositional center); that is, the vector of geometric means of the individual elements rescaled (closed) to be expressed in percentage units in this case. Moreover, the total variance of the data set and the relative contributions of the elements to it are reported (computed from ordinary variances of the centered log-ratio transformation of the composition; raw and percent values shown). It can be observed that the imputation method introduced negligible distortion regarding the center of the data set. The total variation was slightly underestimated, with main differences in contribution being related with the minor elements La and Cu and the major element Ti.

Figure 2 shows the pair-wise log-ratio variances (variances of the log-ratios between each pair of elements; arranged by rows and columns) from the complete and imputed data (displayed in upper and lower triangle respectively). Lower values correspond to higher associations between elements in terms of proportionality. A color scale was used to facilitate

Imputation, Fig. 2 Pair-wise log-ratio variances from complete and imputed data sets (upper and lower triangle respectively)

interpretation, ranging from redder for stronger associations to greener for weaker associations.

In line with the results above, the patterns of associations were very much comparable between complete and imputed data. On the one hand, the strongest associations were generally found among the minor elements, with B being often involved. Major elements Ti and Ce appeared as the most associated with minor elements. On the other hand, the weakest associations were generally found among the major elements, with the highest log-ratio variance being that between P and Ba.

Finally, complete and imputed data sets were visualized in two dimensions using a compositional principal component analysis (PCA) biplot (Fig. 3). The first two principal components (PC1 and PC2) explained similarly moderate 42.35% and 43.87% of the total variability of the respective data sets. Colors and symbols were used to distinguish samples that were complete from those including either nondetects, missing values, or both simultaneously. The overall structure of the data was well preserved after imputation. The length of the links between the arrowheads corresponding to the different elements is related with the log-ratio variances between them. Thus, in agreement with the results showed in Fig. 2, the most independent elements appeared to be P and Ba, particularly with respect to K, Rb, and Li. Obviously, a main factor in

determining the distortion introduced by any imputation method in practice will be the gravity of the missingness problem. We refer the reader to the specialized literature for more detailed discussions about performance in different scenarios.

Summary

Missing data and nondetects are ubiquitous in experimental studies. Ignoring them or treating them carelessly can seriously distort the results and scientific conclusions, particularly where there is a systematic difference between observed and unobserved values. In this sense, it is convenient to investigate why they occurred and make an informed decision about how they could be best handled. Important factors to consider include the severity of the problem, the size of the data set, and the distributional characteristics and nature of the variables involved. Data imputation is a popular approach, and there is a wide range of methods available under different flavors and assumptions. This includes specialized methods for data of compositional nature; that is, data representing relative amounts as frequently found across the geological and environmental sciences.

Independent Component Analysis

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International Institute of Information Technology Bangalore, Electronic City, Bangalore, Karnataka, India

Definition

Independent component analysis (ICA) is a method of decomposing a mixture of signals, i.e., a measured signal, to its individual sources, and is widely understood using its “classical cocktail party” analog (Stone 2002). In a situation at a cocktail party where many people are talking and the speech is captured using a single microphone, ICA is a solution for extracting the different speech signals from the microphone output, given that the voices of different people are unrelated. This process of extraction of source signals is

called “blind source separation” (BSS). An example in geosciences is in using ICA for finding the different rock units in a stream sediment geochemical dataset for mineral exploration (Yang and Cheng 2015).

ICA is formulated as $\mathbf{y} = \mathbf{M}\mathbf{x} + \mathbf{n}$, where $\mathbf{y}$ is the mixed signal, $\mathbf{x}$ is the matrix containing vectors of component signals, $\mathbf{M}$ is the mixing matrix, and $\mathbf{n}$ is the additive noise. If the noise is Gaussian, when using higher-order statistics in the equation, the noise term vanishes. This linear equation, upon removing the noise term, complies with the mixed signal being a linear combination of statistically independent source signals. However, in practice, the ordinary noise-free ICA methods are modified to remove the bias owing to the noise, for implementing the noisy ICA method (Hyvärinen 1999). The $\mathbf{x}$ maximizes a “contrast” function, as introduced by Gassiat in 1988 (Comon 1994), and for which “entropy” value is used. Both $\mathbf{M}$ and $\mathbf{x}$ are unknown, here, and the solution for $\mathbf{x}$ is arrived at when using the Moore–Penrose pseudoinverse of the mixing matrix, i.e., $\mathbf{x} = \mathbf{M}^\dagger \mathbf{y}$, and when $\mathbf{x}$ has maximum entropy.

Overview

The term independent component analysis was introduced by Herault and Jutten circa 1986 (Comon 1994), owing to its similarity with principal component analysis (PCA). A brief history of ICA and its evolution has been discussed by Comon (1994).

Alternative methods for BSS are PCA, factor analysis (FA), and linear dynamical systems (LDS). In ICA, the source signals, extracted as components, are assumed to be statistically independent and non-Gaussian. Unlike ICA, the popularly used alternative methods, PCA and FA, work on the basic assumption that the source signals are uncorrelated and Gaussian. Statistical independence between two signals implies that the values of one signal have no influence or information on those of the other signal. Being uncorrelated does not imply statistical independence as the value of one signal can provide information on the other signal. Thus, uncorrelated variables can be considered to be *partly independent* (Hyvärinen and Oja 2000). The source signals are extracted as eigenvectors and factors, respectively, in PCA and FA. In ICA and PCA, the source signals are referred to as “components.” In PCA, the uncorrelated signals are captured using eigenvectors of the correlation matrix, which are orthogonal components, by design. Thus, PCA removes correlations, which are second-order statistical dependencies, to extract components. That also implies that PCA does not infer higher-order statistical dependencies, e.g., skew and kurtosis. ICA, on the other hand, captures higher-order dependencies. There are known to be similarities between blind deconvolution and ICA (Hyvärinen 1999). When the blind

deconvolution is applied to a signal, which is independently and identically distributed (i.i.d.) over time, it relates closely with ICA.

A widely used data preprocessing step for ICA is the removal of correlations in the signal, referred to as “whitening” the signal. PCA has been used for whitening signals. The extraction of higher-order dependencies is reflected in the non-orthogonality of the components in ICA. The property of statistically independent signals having maximum entropy is exploited in finding independent components. ICA has been widely developed and used in cognitive science for both biomedical data analysis and computational modeling.

Solving PCA using eigenvalue decomposition (EVD) of covariance or correlation matrix is a linear process, whereas removing higher-order dependencies in ICA leads to a multilinear EVD (De Lathauwer et al. 2000). Instead of EVD of correlation matrices, singular value decomposition (SVD) of the raw data can be implemented. There are four widely used algebraic methods using multilinear EVD for solving ICA, namely,

- By means of higher-order eigenvalue decomposition (HOEVD).
- By means of maximal diagonality (MD).
- By means of joint approximate diagonalization of eigenmatrices (JADE).
- By means of simultaneous third-order tensor diagonalization (STOTD).

The HOEVD is the least accurate method, and among the remaining three, MD is the most computationally intensive. Thus, STOTD and JADE algorithms are the preferred methods, of which STOTD is more efficient owing to the readily available tensors that have to be diagonalized, whereas the dominant eigenspaces have to be additionally computed in the case of JADE.

Overall, the ICA algorithm has two aspects, namely, (1) the objective function that maximizes entropy, etc., and (2) the optimization algorithm that influences the algorithmic properties, such as convergence speed, memory complexity, and stability (Hyvärinen 1999). In practice, using stochastic gradient method leads to slower convergence. Hence, a fixed-point algorithm, called FastICA, was proposed by Hyvärinen in 1997 to solve the convergence issue, for which a brief summary is given in Hyvärinen 1999.

Extending the BSS/ICA model from one-dimensional to multidimensional signals, the standard algorithms for ICA can be used for multidimensional ICA (MICA) (Cardoso 1998). This can be done by using a geometric parameterization to avoid using the matrix algebraic technique.

The matrix formulation of noise-free ICA leads to two known ambiguities (Hyvärinen and Oja 2000). Firstly, the variances of the independent components cannot be

determined. Secondly, the order of independent components cannot be determined. This is because all independent components are equally important, unlike the reducing variances in the principal components in PCA that provides the ordering.

Applications

Common applications of ICA include separation of artifacts in the magnetoencephalography (MEG) data of cortical neurons, determination of hidden factors in financial data, and reducing noise in natural images (Hyvärinen and Oja 2000).

Similarly, ICA has also found widespread applicability in geosciences and related areas. When used as exploratory tools for geochemical data analysis, PCA has been found to be useful in finding significant geo-objects, whereas ICA is capable of separating geological populations in the dataset (Yang and Cheng 2015). Hyperspectral images have been classified into thematic land-cover classes using ICA and extended morphological attribute profiles (EAPs) of the images (Dalla Mura et al. 2010). The morphological attribute profiles are first computed for capturing the multiscale variation in geometry. Then, they are applied to the independent components of the image, computed using ICA. The support vector machine (SVM) classifier is then used with the EAPs for classification. ICA has been found to give more accurate classification outcomes than PCA for this application. Similarly, ICA has been useful for analyzing the variability of tropical sea surface temperature (SST) owing to its modeling of statistically independent components (Aires et al. 2000). The whitened SST has been found to be a mixture involving variabilities in several timescales in different geographical areas. Hence, ICA is best applicable in identifying the contributing components, which in turn determine the influence of SST variability in the El Niño Southern Oscillations (ENSO). This method has successfully shown the relationship between the SSTs of the northern and southern equatorial Atlantic Ocean through the “dipole,” and between the SSTs of the Pacific and Atlantic Oceans through the ENSO.

Future Scope

Some of the advances in ICA since 2000 include causal relationship analysis, testing independent components, and analysis of three-way datasets (Hyvärinen 2013). There have also been developments in solving for ICA using time-frequency decompositions, modeling distributions of the components, and non-negative models.

In summary, ICA is a powerful data exploratory tool for separating statistically independent and non-Gaussian components from a mixed signal.

Induction, Deduction, and Abduction

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Induction is a method of reasoning from premises that supply some evidence without full assurance of the truth of the conclusion that is reached. It differs from deduction that starts from premises that are correct and lead to conclusions which are certainly true. Abduction is a rarely used form of logical inference advocated by the philosopher Peirce. It starts with observations from which it seeks to draw the simplest and most likely conclusion. All three words are based on the Latin verb “ducere,” meaning to lead. The prefix “de” means “from,” indicating that deduction derives truth from factual

statements; “in” means “toward,” and induction results in a generalization; while “ab” means “away,” i.e., taking away the best explanation.

Introduction

Induction and deduction are philosophical concepts that are more frequently used than abduction, which often is regarded as a kind of induction or as a form of exploratory data analysis. The philosopher Charles Sanders Pierce (see Staat 1993) made a distinction between inference and decision-making under uncertainty on the one hand, and “theorizing” on the other. He called the former induction and the latter abduction. Traditionally, both induction and theorizing are prevalent in the geological sciences where, commonly, limited observations are used to construct 3-D realities often along with their history in geologic time. This process of reconstructing geological realities is prone to uncertainties and has often resulted in fierce debates in the past.

Difficulties in the application of mathematics to solve many types geological problems stem from: (1) the nature of geological phenomena, especially paucity of exposure of bedrock and restriction of observations to a record of past events that have been only partially preserved in the rocks, and (2) the nature of traditional geological methods of research, which are largely nonmathematical (cf. Agterberg 1961, 1974). Induction is prevalent in geology. It could be argued that geology is a science of induction or abduction.

When mathematics is used to solve geologic problems, the parameters must be defined in a manner sufficiently rigorous to permit nontrivial derivations. During the design of models, it is important to keep in mind Chamberlin’s (1897) warning: “The fascinating impressiveness of rigorous mathematical analysis, with its atmosphere of precision and elegance, should not blind us to the defects of the premises that condition the whole process. There is, perhaps no beguilement more insidious and dangerous than an elaborate and elegant mathematical process built upon unfortified premises.” Problems related to mathematical applications in the geosciences will be discussed later in this entry. Special attention will be given to the application of Bayesian data analysis, which serves to change prior probabilities based on induction into posterior probabilities including true evidence.

Induction Versus Deduction in Mathematical Statistics

Mathematical statistics originated as a science during the seventeenth century with the definitions of “probability” in 1654, “expectation” in 1657, and other basic concepts (Hacking 2006) including the first application of a statistical

significance test Arbuthnot (1710). The idea of inductive logic was initially invented by philosophers under the banner “equipossibility” toward the end of the sixteenth century (Hacking 2006), but the idea remained dormant until the second half of the eighteenth century after the publication of the famous paper by Bayes (1763) that contains the general equation (known as Bayes’ rule or postulate):

$$P(A|B) = \frac{P(A) \cdot P(B|A)}{P(B)}$$

where A is a hypothesis (induction) and B is evidence. Proponents of Bayesian statistics included Jeffries (1939) who, in his book “*Theory of Probability*” insisted that inductive probabilities can only be defined in relation to evidence. Jeffries was immediately criticized by R.A. Fisher, who is generally regarded as the father of mathematical statistics, but who dismissed Jeffries’ book with the words: “He makes a logical mistake on the first page which invalidates all the 395 formulae in his book” (cf., Fisher-Box 1978). Jeffries’ “mistake” was to adopt Bayes’ postulate.

Mcgrayve (2011)’s book “*The theory that would not die*” describes in detail how Bayes’ rule emerged triumphant from two centuries of controversy. Bayesian data analysis is well described in Gelman et al. (2013). Examples of geologic examples using “equipossibility” and Bayes’ postulate will be given later in this entry.

Geological Data, Concepts, and Maps

The first geological map was published in 1815. This feat has been well documented by Winchester (2001) in his book: “*The Map that Changed the World – William Smith and the Birth of Modern Geology*.” According to the concept of stratigraphy, strata were deposited successively in the course of geologic time and they are often uniquely characterized by fossils such as ammonites that are strikingly different from age to age. It is remarkable that this fact remained virtually unknown until approximately 1800. There are several other examples of geologic concepts that became only gradually accepted more widely, although they were proposed much earlier in one form or another by individual scientists. The best-known example is plate tectonics: Alfred Wegener (1966) had demonstrated the concept of continental drift convincingly as early as 1912 but this idea only became acceptable in the early 1960s. One reason that this theory initially was rejected by most geoscientists was lack of a plausible mechanism for the movement of continents.

Along similar lines, Staub (1928) had argued that the principal force that controlled mountain building in the Alps was crustal shortening between Africa and Eurasia. Figure 1 (from Agterberg 1961, Fig. 107) shows tectonic sketch maps

Induction, Deduction, and Abduction, Fig. 1 Tectonic sketch maps of Strigno area on in northern Italy and Eastern Alps (after Agterberg 1961). Although area sizes differ by a factor of 1,600, the patterns showing overthrust sheets are similar. Originally, gravity sliding was assumed to be the major cause of these patterns. However, after development of the theory of plate tectonics in the 1960s, it has become

of two areas in the eastern Alps. The area in northern Italy shown at the top of Fig. 1 is 1600× smaller in area than the region for the eastern Alps at the bottom. The tectonic structure of these two regions is similar. Both contain overthrust

apparent that plate collision was the primary driving force of Alpine orogeny. The Strigno overthrust sheets are due to Late Miocene southward movement of the Eurasian plate over the Adria microplate, and the eastern Alpine nappes were formed during the earlier (primarily Oligocene) northward movement of the African plate across the Eurasian plate. (Source: Agterberg 1961, Fig. 107)

sheets with older rocks including crystalline basement overlying much younger rocks. It is now well known that the main structure of the map at the bottom was created during the Oligocene (33.9-23.0 Ma) when the African plate moved

northward over the Eurasian plate. On the other hand, the main structure of the relatively small Strigno area was created much later during the Late Miocene (Tortonian, 11.6–7.3 Ma) when the Eurasian plate moved southward overriding the Adria microplate that originally was part of the African plate.

Another geological idea that was conceived early on, but initially rejected as a figment of the imagination, is what later became known as the Milankovitch theory. Croll (1875) had suggested that the Pleistocene ice ages were caused by variations in the distance between the Earth and the Sun. Milankovitch commenced working on astronomical control of climate in 1913 (Schwarzacher 1993). His detailed calculations of orbital variations were published nearly 30 years later (Milankovitch 1941) showing quantitatively that amount of solar radiation drastically changes our climate. This theory was immediately rejected by climatologists because the changes in solar radiation due to orbital variations are miniscule, and by geologists as well because, stratigraphically, their correlation with ice ages apparently was not very good. However, in the mid-1950, new methods helped to establish the Milankovitch theory beyond any doubt. Subsequently, it resulted in the establishment of two new disciplines: cyclostratigraphy and astrochronology (Hinnov and Hilgen 2012). The latest geologic timescales of the Neogene (23.0–2.59 Ma) and Paleogene (66.0–23.0 Ma) periods are entirely based on astronomical calibrations, and “floating” astrochronologies are available for extended time intervals (multiple millions of years) extending through stages in the geologic timescale belonging to the older periods (Gradstein et al. 2020). The preceding three examples have in common that the underlying geologic processes were anticipated by individual geoscientists but remained in dispute until their existence could be proven mathematically beyond doubts.

Map-Making

A field geologist is concerned with collecting numerous observations from those places where rocks are exposed at the surface. Observation is often hampered by poor exposure. In most areas, 90% or more of the bedrock surface is covered by unconsolidated overburden restricting observation to available exposures; for example, along rivers (cf. Agterberg and Robinson 1972). The existence of these exposures may be a function of the rock properties. In formerly glaciated areas, for example, the only rock that can be seen may be hard knobs of pegmatite or granite, whereas the softer rocks may never be exposed. Of course, drilling and geophysical exploration techniques provide additional information, but bore-holes are expensive and geophysics provides only partial, indirect information on rock composition, facies, age, and other properties of interest.

It can be argued that today most outcrops of bedrock in the world have been visited by competent geologists. Geologic maps at different scales are available for nearly all countries. One of the major accomplishments of stratigraphy is not only that the compositions but also the ages of rocks nearly everywhere at the Earth’s surface now are fairly well known. However, as Harrison (1963) has pointed out, although the outcrops in an area remain more or less the same during the immediate past, the geologic map constructed from them can change significantly over time when new geological concepts become available. A striking example is shown in Fig. 2. Over a 30-year period, the outcrops in this study area that were repeatedly visited by geologists had remained nearly unchanged. Discrepancies in the map patterns reflect changes in the state of geologic knowledge at different points in time.

Many geologists regard mapping as a creative art. From scattered bits of evidence, one must piece together a picture at a reduced scale, which covers at least most of the surface of bedrock in an area. Usually, this cannot be done without a good understanding of the underlying geologic processes that may have been operative at different geologic times. A large amount of interpretation is involved. Many situations can only be evaluated by experts. Although most geologists agree that it is desirable to make a rigorous distinction between facts and interpretation, this is hardly possible in practice, partly because during compilation results for larger regions must be represented at scales of 1: 25,000 or 1: 250,000, or less. Numerous observable features cannot be represented adequately in these scale models. Consequently, there is often significant discrepancy of opinions among geologists that can be bewildering to scientists in other disciplines and to others including decision-makers in government and industry.

Van Bemmelen (1961) has pointed out that the shortcomings of classical methods of geological observation constrain the quantification of geology. Much is left to the “feeling” and experience of the individual geologist. The results of this work, presented in the form of maps, sections, and narratives with hypothetical reconstructions of the geological evolution of a region, do not have the same exactitude as the records and accounts of geophysical and geochemical surveys, which are more readily computerized even though the results may be equally accurate in an interpretive sense. Geophysical and geochemical variables are determined by the characteristics of the bedrock geology which, in any given area, is likely to be nonuniform because of the presence of different rock types, often with abrupt changes at the contacts between them. The heterogeneous nature of the geologic framework will be reflected or masked in these other variables.

Geologists, geophysicists, and geochemists produce different types of maps for the same region. Geophysical measurements are mainly indirect. They include gravity and

Induction, Deduction, and Abduction, Fig. 2 Two geological maps for the same area on the Canadian Shield (after Harrison 1963). Between 1928 and 1958 there was development of conceptual ideas about the

nature of metamorphic processes. This, in turn, resulted in geologists deriving different maps based on the same observations

seismic data, variations in the Earth's magnetic field, and electrical conductivity. They generally are averages of specific properties of rocks over large volumes with intensities of penetration decreasing with distance and depth. Remotely sensed data are very precise and can be subjected to a variety of filtering methods. However, they are restricted to the Earth's surface. Geochemists mainly work with element concentration values determined from chips of rocks in situ, and also from samples of water, mud, soil, or organic material.

Geological Cross-Sections

The facts observed at the surface of the Earth must be correlated with one another; for example, according to a stratigraphic column. Continually, trends must be established and projected into the unknown. This is because rocks are 3-D

media that can only be observed in 2-D. The geologist can look at a rock formation but not inside it. Sound geological concepts are a basic requirement for making 3-D projections.

During the past two centuries, after William Smith, geologists have acquired a remarkably good capability of imagining 3-D configurations by conceptual methods. This skill was not obtained easily. In Fig. 3, according to Nieuwenkamp (1968), an example is shown of a typical geologic extrapolation problem with results strongly depending on initially erroneous theoretical considerations. In the Kinnehulle area in Sweden, the tops of the hills consist of basaltic rocks; sedimentary rocks are exposed on the slopes; granites and gneisses in the valleys. The first two projections into depth for this area were made by a prominent geologist (Von Buch 1842). It can be assumed that today most geologists would quickly arrive at the third 3-D reconstruction (Fig. 3c) by Westergård et al. (1943).

Induction, Deduction, and Abduction, Fig. 3 Schematic sections originally compiled by Nieuwenkamp (1968) showing that a good conceptual understanding of time-dependent geological processes is required for downward extrapolation of geological features observed at the surface of the Earth. Sections A and B are modified after von Buch

(1842) illustrating his genetic interpretation that was based on combining Abraham Werner's theory of Neptunism with von Buch's own firsthand knowledge of volcanoes including Mount Etna in Sicily with a basaltic magma chamber. Section C is after Westergård et al. (1943) (Source: Agterberg 1974, Fig. 1)

At the time of von Buch it was not yet common knowledge that basaltic flows can form extensive flows within sedimentary sequences. The projections in Fig. 3a, b reflect A.G. Werner's early pan-sedimentary theory of "Neptunism" according to which all rocks on Earth were deposited in a primeval ocean. Nieuwenkamp (1968) has demonstrated that this theory was related to philosophical concepts of F.W.J. Schelling and G.W.F. Hegel. When Werner's view was criticized by other early geologists who assumed processes of change during geologic time, Hegel publicly supported Werner by comparing the structure of the Earth with that of a house. One looks at the complete house only and it is trivial that the basement was constructed first and the roof last. Initially, Werner's conceptual model provided an appropriate and temporarily adequate classification system, although von Buch, who was a follower of Werner, rapidly ran into problems during his attempts to apply Neptunism to explain occurrences of rock formations in different parts of Europe. For the Kinnehulle area (Fig. 3) von Buch assumed that the primeval granite became active later changing sediments into gneisses, while the primeval basalt became a source for hypothetical volcanoes. Clearly, 3D time-dependent mapping continues to present important geoscientific challenges. It is likely that in future a major role will be played by new methodologies initially developed in mathematical morphology (Matheron 1981), a subject currently advanced by Sagar (2018) and colleagues.

Conditional Probability and Bayes' Theorem

Suppose that $p(D|B)$ represents the conditional probability that event D occurs given event B (e.g., a mineral deposit D occurring in a small unit cell underlain by rock type B on a geological map). This conditional probability obeys three basic rules (cf. Lindley 1987, p. 18):

1. Convexity: $0 \leq p(D|B) \leq 1$; D occurs with certainty if B logically implies D ; then, $p(D|B) = 1$, and $p(D^c|B) = 0$ where D^c represents the complement of D
2. Addition: $p(B \cup C|D) = p(B|D) + p(C|D) - p(B \cap C|D)$
3. Multiplication: $p(B \cap C|D) = p(B|D) p(C|B \cap D)$

These three basic rules lead to many other rules (cf. Agterberg 2014). For example, replacement of B by $B \cap D$ in the multiplication rule gives: $p(B \cap C|D) = p(B|D) p(C|B \cap D)$. Likewise, it is readily derived that: $p(B \cap C \cap D) = p(B|D) p(C|B \cap D) p(D)$. This leads to Bayes' theorem in odds form:

$$\frac{p(D|B \cap C)}{p(D^c|B \cap C)} = \frac{p(B|C \cap D)}{p(B|C \cap D^c)} \cdot \frac{p(D|C)}{p(D^c|C)}$$

or

$$O(D|B \cap C) = \exp(W_{B \cap C}) \cdot O(D|C)$$

where $O = p/(1-p)$ are the odds corresponding to $p = O/(1 + O)$, and $W_{B \cap C}$ is the “weight of evidence” for occurrence of the event D given B and C . Suppose that the probability p refers to occurrence of a mineral deposit D under a small area on the map (circular or square unit area). Suppose further that B represents a binary indicator pattern, and that C is the study area within which D and B have been determined. Under the assumption of equipossibility (or equiprobability), the prior probability is equal to total number of deposits in the study area divided by total number of unit cells in the study area. Theoretically, C is selected from an infinitely large universe (parent population) with constant probabilities for the relationship between D and B . In practical applications, only one study area is selected per problem and C can be deleted from the preceding equation. Then Bayes’ theorem can be written in the form:

$$\ln O(D|B) = W_B^+ + \ln O(D); \ln O(D|B^c) = W_B^- + \ln O(D)$$

for presence or absence of B , respectively. If the area of the unit cell underlain by B is small in comparison with the total area underlain by B , the odds O are approximately equal to the probability p . The weights satisfy:

$$W_B^+ = \ln \frac{p(B \cap D)}{p(B \cap D^c)}; W_B^- = \ln \frac{p(B^c \cap D)}{p(B^c \cap D^c)}$$

As an example of this type of application of Bayes’ theorem, suppose that a study area C , which is a million times as large as the unit cell, contains 10 mineral deposits; 20% of C is underlain by rock type B , which contains 8 deposits. The prior probability $p(D)$ then is equal to 0.000 01; the posterior probability for a unit cell on B is $p(D|B) = 0.000 04$, and the posterior probability for a unit cell not on B is $p(D|B^c) = 2.5 \times 10^{-6}$. The weights of evidence are $W_B^+ = 0.982$ and $W_B^- = -1.056$, respectively. In this example, the two posterior probabilities can be calculated without use of Bayes’ theorem. However, the weights themselves provide useful information as will be seen in the next section.

The method of weights of evidence modeling was invented by Good (1950). In its original application to mineral resource potential mapping (Agterberg 1989; Bonham-Carter 1994), extensive use was made of medical applications (Spiegelhalter 1986).

Basic Concepts and Artificial Example

Figure 4 illustrates the concept of combining two binary patterns for which it can be assumed that they are related to occurrences of mineral deposits of a given type. Figure 4a shows locations of six hypothetical deposits, the outcrop pattern of a rock type (B) with which several of the deposits may be associated (Fig. 4b), and two lineaments that have

Induction, Deduction, and Abduction, Fig. 4 Artificial example to illustrate the concept of combining two binary patterns related to occurrence of mineral deposits; (a) outcrop pattern of rock type, lineaments,

and mineral deposits; (b) rock type and deposits dilated to unit cells; (c) lineaments dilated to corridors; (d) superposition of three patterns. (Source: Agterberg et al. 1990, Fig. 1)

Induction, Deduction, and Abduction, Fig. 5 Venn diagrams corresponding to areas of binary patterns of Fig. 4; (a) is for Fig. 5.1B; (b) is for Fig. 5.1C; (c) is for Fig. 5.1D (Source: Agterberg et al. 1990, Fig. 2)

been dilatated in Fig. 4c. Within the corridors around the lineaments, the likelihood of locating deposits may be greater than elsewhere in the study area. In Fig. 4b–d, the deposits are surrounded by a small unit area. This permits estimation the unconditional “prior” probability $P(D)$ that a unit area with random location in the study area contains a deposit, as well as the conditional “posterior” probabilities $P(D|B)$, $P(D|C)$, and $P(D|BC)$ that unit areas located on the rock type, within a corridor and both on the rock type and within a corridor contain a deposit. These probabilities are estimated by counting how many deposits occur within the areas occupied by the polygons of their patterns. The relationships between the two patterns (B and C), and the deposits (D) can be represented by Venn diagrams as shown schematically in Fig. 5.

Operations such as creating corridors around line segments on maps and measuring areas can be performed by using Geographic Information Systems (GISs). The Spatial Data Modeller developed by Raines and Bonham-Carter (2007) is an example of a system that provides tools for weights of evidence, logistic regression, fuzzy logic, and neural networks. The availability of excellent software for WofE and WLR has been a factor in promoting widespread usage of these methods. Examples of applications to mapping mineral prospectivity can be found in Carranza (2004), and Porwal et al. (2010).

Bayes’ Rule for One or More Map Layers

When there is a single pattern B , the odds $O(D|B)$ for occurrence of mineralization if B is present is given by the ratio of the following two expressions of Bayes’ rule: $P(D|B) = \frac{P(B|D)P(D)}{P(B)}$; $P(\bar{D}|B) = \frac{P(B|\bar{D})P(\bar{D})}{P(B)}$ where the set $\bar{D}$ represents the complement of D . Consequently, $\ln O(D|B) = \ln O(D) + W^+$ where the positive weight for presence of B is: $W^+ = \ln \frac{P(B|D)}{P(B|\bar{D})}$.

The negative weight for absence of B is: $W^- = \ln \frac{P(\bar{B}|D)}{P(\bar{B}|\bar{D})}$. The result of application of Bayes’ rule applied to a single map layer can be extended by using it as prior probability input for other map layers provided that there is approximate conditional independence (CI) of map layers. The order in which new patterns are added is immaterial. When there are two map patterns as in Fig. 5.1: $P(D|B \cap C) = \frac{P(B \cap C|D)P(D)}{P(B \cap C)}$ and $P(\bar{D}|B \cap C) = \frac{P(B \cap C|\bar{D})P(\bar{D})}{P(B \cap C)}$. Conditional independence of D with respect to B and C implies:

$$P(B \cap C|D) = P(B|D)P(C|D); P(B \cap C|\bar{D}) = P(B|\bar{D})P(C|\bar{D}).$$

Consequently,

$$P(D|B \cap C) = P(D) \frac{P(B|D)P(C|D)}{P(B \cap C)}; P(\bar{D}|B \cap C) = P(\bar{D}) \frac{P(B|\bar{D})P(C|\bar{D})}{P(B \cap C)}.$$

From these two equations it follows that: $\frac{P(D|B \cap C)}{P(\bar{D}|B \cap C)} = \frac{P(D)P(B|D)P(C|D)}{P(\bar{D})P(B|\bar{D})P(C|\bar{D})}$. This expression is equivalent to $\ln O(D|B \cap C) = \ln O(D) + W_1^+ + W_2^+$. The posterior logit on the left side of this equation is the sum of the prior logit and the weights of the two map layers. The posterior probability follows from the posterior logit. Similar expressions apply when either one or both patterns are absent. Cheng (2008) has pointed out that, since it is based on a ratio, the underlying assumption is somewhat weaker than assuming conditional independence of D with respect to B_1 and B_2 . If there are p map layers, the final result is based on prior logit plus the p weights for these map layers. A good WofE strategy is first to achieve approximate conditional independence by pre-processing. A common problem is that final estimated probabilities usually are biased. If there are N deposits in a study area and the sum of all estimated probabilities is written as S ,

Induction, Deduction, and Abduction, Fig. 6 Surficial geology of Oak Ridge Moraine in study area according to Sharpe et al. (1997). (Source: Cheng 2004, Fig. 2)

Flowing vs. Distance from Thick Drift

Induction, Deduction, and Abduction, Fig. 7 Flowing wells versus distance from buffer zone around Oak Ridge Moraine in study area of Fig. 6. (Courtesy of Q. Cheng)

WofE often results in $S > N$. The difference $S - N$ can be tested for statistical significance (Agterberg and Cheng 2002). The main advantage of WofE in comparison with other methods such as weighted logistic regression is transparency in that it is easy to compare weights with one another. On the other hand, the coefficients resulting from logistic regression generally are subject to considerable uncertainty.

The contrast $C = W^+ - W^-$ is the difference between positive and negative weight for a binary map layer. It is a convenient measure for strength of spatial correlation between a point pattern and the map layer (Bonham-Carter et al. 1988; Agterberg 1989). It is somewhat similar to Yule's (1912) "measure of association" $Q = \frac{\alpha-1}{\alpha+1}$ with $\alpha = e^C$. Both C and Q express strength of correlation between two binary variables that only can assume the values 1 (for presence) or -1 (for absence). Like the ordinary correlation coefficient, Q is confined to the interval $[-1, 1]$. If the binary variables are uncorrelated, then $E(Q) = 0$.

If a binary map layer is used as an indicator variable, the probability of occurrence of a deposit is greater when it is present than when it is absent, and W^+ is positive whereas W^- is negative. Consequently, C generally is positive.

However, in a practical application, it may turn out that C is negative. This would mean that the map layer considered is not an indicator variable. In a situation of this type, one could switch presence of the map layer with its absence, so that W^+ and C both become positive (and W^- negative). An excellent strategy often applied in practice is to create corridors of variable width x around linear map features that are either lineaments as in Fig. 4 or contacts between different rock types (e.g., boundaries of intrusive bodies) and to maximize $C(x)$. From $\frac{dQ}{dx} = \frac{2}{(\alpha+1)^2}$ being positive it follows that $Q(x)$ and $C(x)$ reach their maximum value at the same value of x (cf. Agterberg et al. 1990). Alternative approaches to WofE as discussed here have more recently been proposed by Baddeley et al. (2020).

Flowing Wells in the Greater Toronto Area

Cheng (2004) has given the following application of Weights-of-Evidence modeling. Figure 6 shows surficial geology Oak Ridge Moraine (ORM) for a study on assessment of flowing water wells in surficial geology in the Greater Toronto area,

Flowing Wells vs. Distance From High Slope Zone

Induction, Deduction, and Abduction, Fig. 8 Flowing wells versus distance from relatively steep slope zone in study area of Fig. 6. (Courtesy of Q. Cheng)

Ontario. The ORM is a 150 km long east-west trending belt of stratified glaciofluvial-glaciolacustrine deposits. It is 5–15 km wide and up to 150 m thick. For more detailed discussion of the geology of ORM, see Sharpe et al. (1997). It is generally recognized that the ORM is the main source of recharge in the area. Figures 7 and 8 show flowing wells together with two map patterns related to ORM thought to be relevant for flowing well occurrence.

Cheng (2004) used Weights-of-Evidence to test the influence of the ORM on locations of flowing wells. A number of binary patterns were constructed by maximizing the contrast C for distance from ORM. C reaches its maximum at 2 km meaning that a YES-NO binary pattern with YES on points belonging to ORM plus all points that occur less than 2 km from ORM, and NO for the remainder of the study area with points that are on ORM plus points more than 2 km away from ORM provides positive and negative weight that would be best to use for a binary pattern of enlarged ORM for which the contrast $C = W^+ - W^-$ reaches its maximum value of spatial correlation.

Two other binary patterns constructed in the same way by Cheng (2004) were distance from enlarged ORM (Fig. 7), and

distance from a relatively thick glacial drift layer (Fig. 8). The posterior probability map shown in Fig. 9 is based on binary maps at which the spatial correlation reaches their maximum values in Figs. 7 and 8, respectively. It not only quantifies the relationship between the known artesian aquifers and these two binary map layers, it also outlines areas with no or relatively few aquifers that have good potential for additional aquifers.

Summary and Conclusions

The philosophical terms “induction” and “deduction” are more frequently used than “abduction.” Induction is a method of reasoning from premises that supply some evidence without full assurance of the truth of the conclusion that is reached. It differs from deduction that starts from premises that are correct and leads to conclusions that are certainly true. Abduction starts with observations from which it seeks to find the simplest and most likely conclusion. Originally, geology was a science of induction and abduction.

Posterior Probability Map calculated by Arc-WofE from buffer zones around ORM and steep slope zones

Induction, Deduction, and Abduction, Fig. 9 Posterior probability map for flowing wells based on buffer zone around Oak Ridge Moraine (Fig. 7) and steep slope zone area (Fig. 8) in study area. (Courtesy of Q. Cheng)

Mathematical statistics commenced as a science of deduction. Induction was introduced slowly with the concept of “equiprobability” and after increasing popularity of Bayes’ rule. Until recently, there remained significant disagreement between Bayesian statisticians and those, sometimes called “frequentists,” who avoided subjective notions in their statistical modeling. Bayesian data analysis aims to improve estimates of statistical parameters initially obtained by subjective reasoning. In the example of flowing wells given in this entry the prior probabilities are based on the assumption that the wells are randomly distributed across the study area but the posterior probabilities incorporate various types of evidence pertaining to the geographic locations of the wells.

IGSN

Definition

IGSN (International Generic Sample Number) is a persistent identifier for material samples and specimens. Material samples (also referred to as physical samples) include objects such as cores, minerals, fossil specimens, synthetic specimens, water samples, and more. The concept of the IGSN was originally developed for the earth sciences but has seen growing adoption in other domains including, but not limited to, natural and environmental sciences, materials sciences, physical anthropology, and archaeology.

Persistent identifiers are unique labels given to an object (often a digital resource) in order to facilitate unique identification. In the case of IGSN, the identifier is assigned as part of a metadata record representing a material sample. The metadata record includes provenance and other information from along the samples lifecycle such as where the sample was collected, who collected it, and descriptive metadata ranging from spatial coordinates, collection method, mineral classification to identifiers for related publications. Once an IGSN is assigned, it does not change, it is persistent and globally unique. The metadata record may be updated but the identifier will remain unchanged. IGSN provides sample citations in the literature which can be used to unambiguously track a sample and build connections between data and analysis derived from the same samples in different applications (Conze et al. 2017).

A key feature of an IGSN is that it is “resolvable.” IGSNs can be used to retrieve sample metadata by using Internet protocols to obtain the digital resource the IGSN identifies.

IGSN uses the Handle system (<http://www.handle.net/>), the same technical infrastructure used by Digital Object Identifiers (DOIs), to resolve an IGSN to the appropriate resource location on the web. To resolve an IGSN, one would append the URL “<https://hdl.handle.net/10273/>” with the identifier. For example, to resolve the IGSN “BFBG-154433,” visit <https://hdl.handle.net/10273/BFBG-154433>. The resulting URL will “resolve” to the webpage hosting the metadata profile for the sample represented by the IGSN.

While IGSN functions similarly to DOIs, they do have important differences. DOIs are used to identify objects like journal articles, publications, and datasets. DOIs have standard metadata requirements, which are optimized for the types of objects they support. IGSN have metadata requirements that are tailored to material samples. They include metadata fields that document the scientific nature of the samples and their provenance. The metadata fields can be community specific, capturing the critical metadata for a particular community or domain.

IGSNs, like other persistent identifiers, are important because they help support data management and comply with the principles system for making scientific data and samples FAIR: findable, accessible, interoperable, and reusable (Wilkinson et al. 2016). FAIR samples support reproducible research, enable access to publicly funded assets, and allow researchers to leverage existing research investments by way of new analytical techniques or by augmenting existing data through reanalysis. For example, the use of IGSN allows scientists to unambiguously link analytical data for individual samples which were generated in different labs and published in different articles or data systems. Ultimately these identifiers will allow researchers to link data, literature, investigators, institutions, etc., creating an “Internet of samples” (Wyborn et al. 2017). IGSNs are a recommended persistent identifier by the Coalition for Publishing Data in the Earth and Space Sciences (COPDESS) and publishers such as AGU and Elsevier.

History and Evolution of IGSN

The concept of the IGSN was developed in 2004 at the Lamont-Doherty Earth Observatory at Columbia University with support from the National Science Foundation (NSF) (Lehnert et al. 2004). The first registration agent (also known as an allocating agent) to issue IGSNs was SESAR, the System for Earth Sample Registration (www.geosamples.org). The IGSN e.V. (www.igsn.org), the implementation organization of the IGSN, was formed in 2011. It is an international, member based, nonprofit organization which oversees the federated IGSN registration service and operates the IGSN Central Registry. The IGSN e.V. has more than 20 members (full and affiliate). The members are defined as

organizations who operate or are developing an allocating agent. Affiliate members are organizations which support the IGSN community and use existing allocating agents for sample registration. As part of the federated IGSN system, allocating agents “allocate” IGSN identifiers and ensure the persistence of metadata records and IGSN metadata profile pages.

In 2018, the Alfred P. Sloan Foundation funded the IGSN 2040 project “to re-design and mature the existing organization and technical architecture of the IGSN to create a global, scalable, and sustainable technical and organizational infrastructure for persistent unique identifiers (PID) of material samples” (IGSN e.V. 2019). The primary outcomes of the project have led to negotiations with DataCite to establish a partnership which will provide scalable and sustained IGSN registration, development of a samples “Community of Communities” to scale activities such as standards for sample identifiers, community engagement, broader adoption of IGSN, and a redesigned technical architecture which embraces modern web technologies (Lehnert et al. 2021a).

Current System Architecture of the IGSN e.V.

In simplified terms, the IGSN system architecture (Fig. 1) is made up of four roles: the IGSN Central Registry, allocating agents, end users, and metadata portals. As previously mentioned, the **IGSN Central Registry** is based on the Handle System. The Handle System is a distributed system for assigning identifiers (handles) for digital objects while ensuring that the identifier is unique and persistent (Arms and Ely 1995). The IGSN Central Registry is a global server which stores the identifiers, registration metadata about the objects being identified, and provides a service to resolve identifiers. The IGSN Central Registry uses a REST API (<https://doibb.wdc-terra.org/igsn/static/apidoc>) for its federated registration service.

International Generic Sample Number, Fig. 1 Simplified system architecture of the IGSN registration. Source: <https://igsn.github.io/system/>

Allocating agents are the local service providers. They provide a range of services including registration (or minting) services to one or more sample repositories or data centers. See Table 1 below for a list of IGSN allocating agents and the community they serve. New agents will emerge as new communities adopt IGSN.

Allocating agents capture registration metadata and descriptive metadata, which make up the IGSN metadata kernel. Registration metadata are the metadata elements required for the registration and administration of IGSN (<http://schema.igsn.org/registration/>). Descriptive metadata are dependent on the “community of practice” of the allocating agent and capture information used to catalog samples. This metadata is used to support discovery and access to samples. Descriptive metadata are not stored by the IGSN Central Registry. Allocating agents are responsible for storing the descriptive metadata and providing access to it for harvesting using the IGSN metadata kernel or Dublin Core.

End users of IGSN range from individual researchers or research teams to curators at sample repositories or museums. They may be using IGSN in their management of material sample collections, small and large. These users make decisions about what samples to register with IGSN and create metadata records. They register their sample metadata at an allocating agent. Allocating agents ensure the persistence of the submitted metadata and, depending on the agent, may provide curatorial review of the records to ensure they adhere to community standards. Ultimately, the users are responsible for maintaining the accuracy and quality of their metadata content. End users of IGSN also include those looking for existing samples to reuse. Samples may be reused in new and different ways or to validate previous work. Rich descriptive metadata allows new users to evaluate existing samples and may help to reduce the need to conduct field research to gather new samples at the same site.

Metadata portals are sample catalogs which harvest metadata from IGSN allocating agents. These metadata portals are used to support discovery and access to material samples. Metadata portals harvest sample metadata from allocating agents using the Open Archives Initiative Protocol for Metadata Harvesting (OAI-PMH) protocols. IGSN metadata portals serve specific communities of practice. The various sample communities require different metadata to identify and describe the scientific qualities of their research objects as defined by their community. There isn’t a “one size fits all” approach to sample metadata. Example community portals can be viewed at <http://igsn2.csiro.au/> and <http://www.geosamples.org/>.

Syntax and Metadata

IGSN are represented by string values which can contain the following characters `^[A-Za-z]{2-4}[A-Za-z0-9.-]{1-71}$`. They are not intended to be read by humans but can contain some information embedded in the identifier. IGSN begins

System for Earth Sample Registration (SESAR)	http://www.geosamples.org/	Supports registration by the general public

with a prefix which includes “super-namespace” codes among the characters which represent the allocating agent where the IGSNs were minted (e.g., AU for Geoscience Australia). At SESAR, IGSNs have a five-digit prefix, which includes the super-namespace code IE, followed by a three-character personal namespace selected by the user. IGSNs are typically less than 20 characters in length (e.g., AU999971; IEUJA0011; ICDP5054EHW1001). The remaining characters after the super-namespace and personal namespace are randomly assigned during the registration process. Depending on the allocating agent, the characters after the super-namespace and personal namespace may also be user assigned.

There are some exceptions to the five-digit prefix. IGSNs registered at SESAR before the founding of the IGSN e.V. are grandfathered in with three-digit prefixes. These IGSN do not include the super-namespace code signifying the allocating agent where the samples were registered. This concept of the super-namespace was added once the federated concept of the IGSN e.V. was developed.

IGSN operates using the handle-namespace “10273.” The address of the IGSN resolver is <http://hdl.handle.net/10273>. As previously outlined, IGSN can be resolved by appending the IGSN to this address, for example, <http://hdl.handle.net/10273/IEUJA0011>. This address then redirects to the metadata profile page (Fig. 2) maintained by the allocating agent which registered the sample.

As previously mentioned, the IGSN metadata kernel is divided into two major categories, registration metadata and descriptive metadata. Registration metadata are the metadata elements required by the IGSN e.V. as part of the minting process. Descriptive metadata are dependent on the community of practice of the allocating agent. The IGSN e.V. has a

suggested list of descriptive metadata which “provide a minimum set of elements to describe a geological sample. The schema only contains elements that do not change over time, in analogy to being a ‘birth certificate’ of a sample” (IGSN e.V. 2016). Descriptive metadata is not prescribed by the IGSN e.V. as the allocating agents are best situated to determine what metadata is required to support their community of practice. The IGSN metadata kernel aligns with the DataCite Metadata Schema 4.0.

Future Technical Architecture of the IGSN

In order to increase the sustainability and scale IGSN registration capabilities to the billions, the IGSN 2040 project has developed a new architecture for the IGSN system and services (Klump et al. 2020). The redesign involves moving from XML based metadata schemas to using web architecture principles where metadata would be stored using JSON-LD. The use of JSON-LD will allow allocating agents greater flexibility in supporting community specific variations on their metadata profiles. Ultimately the use of web architecture principles will support the scaling of publishing and harvesting of IGSNs to billions of samples, which will lead to broader services for metadata portals (referred to as metadata aggregators in the proposed architecture) and end users. These services include the support of knowledge graphs which might connect samples to other related identifiers or resources.

Adoption of IGSN

As of 2021, nearly ten million samples have been registered with IGSN. IGSN has been adopted by geological surveys in

the USA, the UK, Australia, Korea, and other organizations and universities globally. In the USA, current users include the Smithsonian Institution, the US Department of Energy, NOAA-NCEI, US core repositories, and the International Continental Drilling Program.

IGSN is a recommended best practice in support of Open and FAIR samples by publishers and sample focused communities. IGSN can be used to track samples and link sample data along its lifecycle from field collection to analysis and publication and to archive and reuse. IGSN are being incorporated into data systems in order to create an efficient, collaborative pipeline (Lehnert et al. 2021b). This includes iSamples (www.isamples.org), StraboSpot (www.strabospot.org), EarthChem (www.earthchem.org), SPARROW (sparrow-data.org), and Macrostrat (www.macrostrat.org).

Moving Forward

IGSN e.V. and DataCite will finalize their partnership in late 2021. As a result, the system and technical architecture of the IGSN may undergo some changes. This includes the implementation of the newly developed technical architecture built on web architecture principles.

As interest and adoption of IGSN are expanding beyond the earth sciences, the IGSN e.V. will be changing the definition of the IGSN acronym. The change from geo to something more inclusive will better represent the diverse sample community around the IGSN. The change is expected to be announced in early 2022.

Summary

IGSN is a persistent identifier for material samples and specimens. They are used as citations to samples which can be tracked throughout their lifecycle. IGSN are globally unique and are resolvable, meaning they use Internet protocols to direct users to a persistent webpage which hosts metadata about the sample they represent. IGSN can be obtained from one of the allocating agents listed in Table 1. Allocating agents represent different communities of practice and may have different requirements for the descriptive metadata about a sample. The IGSN e.V., the implementation office of the IGSN, supports the IGSN Central Registry. Allocating agents mint IGSN through the Central Registry and must make their sample metadata available for harvesting by metadata portals. Allocating agents may offer these services themselves. The IGSN 2040 project made recommendations to scale the IGSN towards the future. This includes a partnership with DataCite and the design of a web architecture-based system. These changes will enable broader services related to the IGSN and allow IGSN to scale towards the future.

Interpolation

Jaya Sreevalsan-Nair
Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Interpolation is the methodology by which unknown values of a variable are computed within a range of discrete data points using their known values. These values, both known and unknown, are governed by the assumption of an underlying continuous function. Interpolation involves identifying or approximating this continuous function, which is then used to compute the values at desired data points.

Definition and History

For interpolation of a single variable x , the ordered set of tuples $\mathcal{S}$ is known, such that $\mathcal{S} = \{(x_0, y_0), (x_1, y_1), \dots, (x_n, y_n)\}$, where x_i for $i = 0, 1, \dots, n$ is sorted in increasing order, then the interpolating function, or *interpolant*, $f(x)$ is determined, such that $f(x_i) = y_i \forall i \in [0, n]$, and $i \in \mathbb{Z}^+$. This is referred to as *univariate interpolation*. Hereafter, the “data points” (x, y) will be simply referred to as “points” for the sake of readability. Similarly, *multivariate interpolation* deals with interpolation of multiple variables, which can be seen analogous to reconstruction of a continuous function in a multi-dimensional space. These functions are represented in the form of polynomials.

Thorvald Thiele has defined in his book *Interpolationsrechnung* in 1909 that interpolation is the “art of reading between the lines in a numerical table” (Meijering 2002). In science and engineering, mathematically modeling discrete values as a continuous function gives a *tensor field*, which is a generalization of scalar field and vector field in its zeroth and first order, respectively. The discrete points, which are used for determining the interpolant, are obtained through sampling, observation, or experimentation. Interpolation is the process by which the continuous function of a variable or the field is reconstructed from its discrete values. In this regard, sampling based on Nyquist theorem is appropriately needed to reduce reconstruction error. In the scope of reconstruction, there is a salient difference between approximation and interpolation. The approximation theorem states that every continuous function on a closed interval can be approximated uniformly by a polynomial to a predetermined accuracy. However, the approximating function, unlike the interpolating one, need not guarantee that the function value at the discrete points is equal to the known values.

The history of interpolation dates back to seventeenth century in the age of scientific revolution, even though there is evidence of usage of history in texts from ancient Babylon and Greece, the early medieval China and India, and the late medieval Arab, Persia, and India (Meijering 2002). Interpolation theory was further developed in the Western countries by scientists, notably including Copernicus, Kepler, Galileo, Newton, and Lagrange, to promote their work in astronomy and physics.

Univariate Interpolation

The simplest forms of interpolation are implemented using univariate interpolants. There are several widely used interpolants – linear, piecewise linear, polynomial, trigonometric interpolants, etc. Linear interpolation is by far the most popular one used across different domains as it has the best tradeoff between accuracy and efficiency. The criteria for picking an interpolant for a specific computational application

Interpolation, Fig. 1 Piecewise linear interpolation generated by adding points progressively. The newly added points are annotated by the red circles on the visualization of linear interpolation. (Image source:

The screenshots of visualization of the interpolation were generated from an online browser-based application, Online Tools, developed by Timo Denk, <https://tools.timodenk.com>)

depend on both the required accuracy and its efficiency, measured using the computation time. For example, computer graphics applications, including geovisualization, use linear interpolation owing to two reasons. Firstly, the prescribed accuracy for the color mapping, i.e., mapping colors to real values, is limited by the human perception of color. Secondly, the expected computational efficiency is in creating interactive graphical user interface (GUI) applications. Linear interpolation entails finding the line equation for given two points, described by the two tuples of (x, y) values. For two discrete points $(x_1, f(x_1))$ and $(x_2, f(x_2))$, the linear interpolant is given by $f(x) = \frac{f(x_2) - f(x_1)}{x_2 - x_1} \cdot (x - x_1) + f(x_1)$.

In order to reduce the reconstruction error, linear interpolation can be extended as *piecewise linear interpolation*, which introduces linear interpolants between two consecutive tuples in the ordered list of the tuples, sorted by their x -value. Figure 1 shows how the piecewise linear interpolation can be progressively generated. The degree of the interpolant can be increased by including more points to generate each interpolant, as shown in Fig. 2. In such a scenario, each interpolant between a curve is substituted by an interpolant of a higher degree using derivatives in the case of quadratic function and knots in a spline function in the case of a cubic spline function.

Extending the examples so far, each segment in the piecewise interpolants can include more than two points, thus using n points in each segment to have a polynomial interpolant of degree $(n - 1)$, at the most. The key aspect of piecewise interpolants is that the points at the end of the segment guarantee up to C^0 continuity, i.e., continuity by the function value or the zeroth derivative.

The interpolant type and application revolve around the mathematical function that gives the function values at the sample points. Apart from polynomials, the interpolants can be exponential, logarithmic, trigonometric, etc. There are also specific interpolation methods through the use of Gaussian processes, such as kriging, which has several variants of its own, e.g., simple, ordinary, and regression kriging (see the chapter on “Kriging” for more details).

Multivariate Interpolation

Now, interpolation can be extended from a single variable to multiple ones. Multivariate interpolation leads to higher dimensional interpolation, e.g., bilinear, and trilinear interpolants. These extensions of linear interpolants involve independent interpolation across different dimensions. This is

Interpolation, Fig. 2 Increasing the degree of interpolation in piecewise functions for the same set of points used in piecewise linear interpolation given in Fig. 1, going from linear to quadratic to cubic,

done by adding more points that are interpolated in one dimension, but used as sample points in another dimension, with the constraint that all dimensions are used for interpolation only once.

For two-dimensional (2D) and three-dimensional (3D) spatial applications, it is important to discuss bivariate and trivariate interpolation, respectively. As already discussed, interpolation involves the identification of the known values that would generate the interpolant. These known values in all applications are essentially immediate or local neighbors. Finding neighborhoods is straightforward in gridded and structured datasets as the indices, which are used to search and retrieve a point, are also helpful in finding the neighbors. For instance, in a 3D lattice structure, a grid or lattice point $P(i, j, k)$ with indices along x , y , and z axes, respectively, has 26 local neighbors whose indices are constrained within $[i - 1, i + 1]$, $[j - 1, j + 1]$, and $[k - 1, k + 1]$ simultaneously.

However, in the case of scattered (2D or 3D) points, there are several methods that could be used once neighbors are identified. Identifying neighbors is conventionally based on sorting the distance between the concerned point and the plausible neighboring points. Several constraints can be applied as neighborhood search criteria, e.g., spherical radius and k -nearest neighbors. Since the neighborhood is determined using the distance measure, which itself could be the

from left to right. (Image source: The screenshots of visualization of the interpolation were generated from an online browser-based application, Online Tools, developed by Timo Denk, <https://tools.timodenk.com>)

conventionally used Euclidean, or Hamming, Chebyshev, etc., special interpolants are used for scattered points. These include Shepard's method [inverse distance weighting (IDW)] (Shepard 1968), Sibson's interpolation (natural neighbor interpolation) (Sibson 1981), and radial basis function interpolation (Hardy 1971). These interpolants have a global as well as a local variant. In the global variant, all points are considered, whereas only local neighbors are considered in the local variant of the interpolant. The global or the local extent of the points considered is selected for computing weights for the known values. Consider the case of IDW to understand the weighting process better, where the interpolant $f(\mathbf{x})$ is computed using n selected points, such that, $\mathbf{x}, \mathbf{x}_i \in \mathbb{R}^d$, i.e., d -dimensional space, and $f(\mathbf{x}_i)$ are the known values. Then, with distance between $\mathbf{x}$ and $\mathbf{y}$ given as $d(\mathbf{x}, \mathbf{y})$ and the distance-decay parameter $p \in \mathbb{Z}^+$,

$$f(\mathbf{x}) = \begin{cases} f(\mathbf{x}_k), & \text{if } d(\mathbf{x}, \mathbf{x}_k) = 0, \text{ where } i = k, \\ \frac{\sum_{i=1}^n w_i(\mathbf{x}) f(\mathbf{x}_i)}{\sum_{i=1}^n w_i(\mathbf{x})}, & \\ \text{else } d(\mathbf{x}, \mathbf{x}_i) \neq 0, \forall i \text{ and } w_i(\mathbf{x}) = (d(\mathbf{x}, \mathbf{x}_i))^{(-p)} \end{cases}$$

In a variant of IDW, the distance-decay parameter has been adaptively computed using the point pattern of the local neighborhood (Lu and Wong 2008). IDW and its adaptive

variants have been routinely used for 3D geological modeling (Liu et al. 2021).

Applications

There are several uses of interpolation, of which data visualization has several applications. Contour extraction is a visualization technique that entails the use of linear interpolation and its higher-dimensional variants in gridded datasets for finding contour lines in 2D and isosurfaces in 3D space. Contour lines are computed using Marching Squares and isosurfaces using the Marching Cubes method (Lorensen and Cline 1987), in 2D and 3D datasets, respectively. Contour lines or isosurfaces are defined as a locus of points all having the same function value. For example, contour tracking has been effectively used for superresolution border segmentation of remotely sensed images for geomorphologic studies (Cipolletti et al. 2012).

Linear interpolation is also widely used in several visualization techniques such as streamline computation, direct volume rendering, graphical rendering techniques with shading models, etc. In visualization, linear interpolation is used in

color mapping that has varied applications, such as choropleth maps, i.e., cartographic maps with colors in regions within geopolitical or other boundaries. As shown in Fig. 3, the color legend in the choropleth map indicates how color is linearly interpolated based on the known values and discretized for the numerical bins of the values.

The choice of interpolation techniques is based on performance – efficiency and accuracy. Reconstruction errors are to be studied for the latter. Apart from these metrics, the level of continuity that is needed from the interpolant, e.g., C^0 , C^1 continuity, is determined by the application, and it governs the choice of the interpolant.

Future Scope

Interpolation has been ubiquitous for mathematical modeling required for a variety of applications in geoscience. It has found its place as a key step in modern data science workflows, such as deep learning. For instance, residual learning networks (ResNets) have been used for seismic data interpolation (Wang et al. 2019).

Synonyms

H-spread; Middle 50%; Midsread

Definition

The interquartile range is a measure of dispersion or scale based on order statistics.

Consider the univariate sample $\mathbf{x} = (x_1, x_2, \dots, x_n)$. For simplicity, assume that the sample size n is such that $n/4$ is an integer. Denote $\tilde{\mathbf{x}} = (x_{1:n}, x_{2:n}, \dots, x_{n:n})$ the sample $\mathbf{x}$ sorted

in nondecreasing order, i.e., $x_{1:n} \leq x_{2:n} \leq \dots \leq x_{n:n}$ are the order statistics of the sample. The lower quartile is $q_{1/4}(\mathbf{x}) = x_{\frac{n}{4}:n}$, the upper quartile is $q_{3/4}(\mathbf{x}) = x_{\frac{3n}{4}:n}$, and the interquartile range is $\text{IQR}(\mathbf{x}) = q_{3/4}(\mathbf{x}) - q_{1/4}(\mathbf{x})$. Sample sizes for which $n/4$ is not an integer require a special definition.

Usage and Interpretation

The interquartile range is analogous to the standard deviation in the sense that it measures the dispersion or scale of a sample. While the standard deviation computes the spread around the mean, the interquartile range depends on the sample's order statistics. The interquartile range is, therefore, a robust measure in the sense that a few outlying observations have little or no effect on it. Such robustness justifies the use of the interquartile range in outlier identification procedures.

If $X \sim N(\mu, \sigma^2)$ denotes a random variable with mean $\mu \in \mathbb{R}$ and standard deviation $\sigma > 0$, then its interquartile range is $2\sigma\phi^{-1}(3/4)$, where ϕ is its cumulative distribution function. This value can be approximated by 1.349σ or by $27\sigma/20$. With this in mind, the sample standard deviation and $20/27$ times the interquartile range of the sample are comparable, provided the data are outcomes of independent identically distributed random variables $N(\mu, \sigma^2)$ -distributed. Comparing these two quantities is a simple way of checking this last hypothesis.

The interquartile range appears in the boxplot as the distance between the hinges.

Definitions for All Cases of $n \geq 4$

Hyndman and Fan (1996) provide a detailed discussion about the ways in which order statistics can be computed. These definitions are different estimators of the quantiles of a distribution.

The (population or distributional) quantile $\alpha \in (0, 1)$ of a distribution is

$$Q_\alpha = F^-(\alpha) = \inf_{x \in \mathbb{R}} \{F(x) \geq \alpha\},$$

where F is the cumulative distribution function that characterizes the distribution of the random variable X . This definition encompasses all types of distributions. Three values of α render well-known names: $Q_{1/4}$ is the lower or first quartile, $Q_{1/2}$ is the median or second quartile, and $Q_{3/4}$ is the upper or third quartile.

The thick red line in Fig. 1 shows the cumulative distribution function of a beta random variable with both shape parameters equal to 3, i.e.,

Interquartile Range, Fig. 1 Populational and sample quantiles

$$F(x) = \begin{cases} 0 & \text{if } x < 0, \\ \frac{x^3}{3} - \frac{x^4}{2} + \frac{x^5}{5} & \text{if } 0 \leq x \leq 1, \\ 1 & \text{if } x > 1. \end{cases} \quad (1)$$

The population (or “distributional”) first quartile, the median, and the third quartile are, respectively, $Q_{1/4} = 0.359436$, $Q_{1/2} = 1/2$, and $Q_{3/4} = 0.640564$ (the first and last values were obtained numerically). The red arrows in Fig. 1 show how they stem as the inverse of F .

Figure 1 also shows a classical estimator of F based on the sample $\mathbf{x} = (x_1, x_2, \dots, x_n)$, namely, the empirical cumulative distribution function $\hat{F}(\mathbf{x})$:

$$\hat{F}(t) = \frac{1}{n} \# \{ \ell : x_\ell \leq t \}, \text{ for every } t \in \mathbb{R},$$

where we omitted the dependence of $\hat{F}$ on $\mathbf{x}$, and $\#A$ denotes the cardinality of the set A . This function appears as “stairs” of intervals closed to the left and open to the right, and height $1/n$. This function, or any other estimator of F , is the basis for computing sample quantiles of arbitrary order.

We now take a sample of size $n = 12$ from the Beta distribution characterized by the cumulative distribution function given in (1). This particular sample $\mathbf{x}$ is such that the first and third quartiles are $q_{1/4} = x_{3:12} = 0.29$, and $q_{3/4} = x_{9:12} = 0.70$ (after rounding). Black arrows show their position, and we notice that $q_{1/4} < Q_{1/4}$, and that $q_{3/4} > Q_{3/4}$.

In this case, we computed the sample median as the midpoint between $x_{6:n}^q$ and $x_{7:n}^q$. After rounding, its value is $q_{1/2} = 0.55$ and, therefore, $q_{1/2} > Q_{1/2}$. Similar approaches are taken to

compute the first and fourth quartiles of samples of sizes n such that $n/4 \notin \mathbb{N}$.

Hyndman and Fan (1996) define nine ways of computing $q_\alpha(\mathbf{x})$, for $\alpha \in (0, 1)$. All of these approaches are a weighted average of consecutive order statistics:

$$^{(i)}q_\alpha(\mathbf{x}) = (1 - ^{(i)}\gamma)x_{j:n} + ^{(i)}\gamma x_{j+1:n}, \quad (2)$$

where $i = 1, 2, \dots, 9$ is the method, $\frac{i-m}{n} \leq \alpha \leq \frac{i-m+1}{n}$, and $^{(i)}\gamma$ is a function of $j = \lfloor an + m \rfloor$ and $g = an + m - j$.

Any method should satisfy the following properties:

P1) $^{(i)}q_\alpha(\mathbf{x})$ is continuous on $\alpha \in (0, 1)$.

P2) The usual definition of median is respected:

$$^{(i)}q_{1/2}(\mathbf{x}) = \begin{cases} x_{\frac{n+1}{2}:n} & \text{if } n \text{ is odd,} \\ \frac{x_{\frac{n}{2}:n}^q + x_{\frac{n}{2}+1:n}^q}{2} & \text{if } n \text{ is even.} \end{cases}$$

P3) The tails of the sample are treated equally:

$$\# \{ \ell : x_\ell \leq ^{(i)}q_\alpha(\mathbf{x}) \} = \# \{ \ell : x_\ell \geq ^{(i)}q_{1-\alpha}(\mathbf{x}) \}.$$

P4) The sample and distributional quantiles are analogous, i.e.,

$$\# \{ \ell : x_\ell \leq ^{(i)}q_\alpha(\mathbf{x}) \} \geq \alpha n.$$

P5) Where the inverse $^{(i)}q^{-1}(x)$ is uniquely defined, holds that

- a) ${}^{(i)}q^{-1}(x_{1:n}) > 0$ and that ${}^{(i)}q^{-1}(x_{n:n}) < 1$,
 b) ${}^{(i)}q^{-1}(x_{k:n}) + {}^{(i)}q^{-1}(x_{n-k+1:n}) = 1$.

The `quantile` function provided by the R platform (R Core Team 2020) implements the nine alternatives discussed by Hyndman and Fan (1996), being $i = 7$ the one that operates unless another one is requested. It is noteworthy that only one of these options satisfies all the properties stated above, namely, $i = 5$. Nevertheless, the recommended one is $i = 8$ because of its approximate unbiasedness.

Summary

The Interquartile range is a measure of scale or spread based on order statistics. As there are many ways of computing such quantities, it is recommended to state which version was used in practice.

Inverse Distance Weight

Narayan Panigrahi
 Scientist and Head of GIS Division, Center for Artificial Intelligence and Robotics (CAIR), Bangalore, India

Definition

This entry discusses one of the widely used spatial Interpolation method, the IDW (inverse distance weight) and its variants. The entry starts with the genesis and historic development of IDW, its definition, and its mathematical basis. The factors governing the IDW are discussed. The selections of the sample values depending on the neighborhood policy are discussed. Also discussed are some interesting mathematical variations of the method which makes it useful in various different phenomena with varying spatial distribution of sample locations. Finally the variants of the

method in 3D and its usage are discussed. The chapter ends with some important recommendations and scenario so as which variant to use in which application.

Genesis and Historic Development of IDW

Inverse Distance Weighting (IDW) is a type of deterministic method for multivariate spatial interpolation technique to interpolate the value at an location from known sampled locations scattered around the point of interest. The assigned values to unknown points are computed with a weighted average of the values available at the surrounding known locations.

IDW is a multivariate spatial interpolation technique which is easy to implement through computer programming. Computing the magnitude of missing spatial data of a location from among the given measured data of the phenomena such as height, pollution density, snow precipitation, and temperature is easier using IDW. It mimics the natural phenomena more closely in comparison to other spatial interpolation techniques.

The name IDW is because the methods use the weighted average of distance from the point of unknown data to data point where the value of the sample is known which is applied to compute the value of unknown value. Since it resorts to the inverse of the distance to each known point (“amount of proximity”) when assigning weights it is known as inverse distance weight.

The method IDW owes its genesis at the Harvard Laboratory for Computer Graphics and Spatial Analysis. At the beginning of 1965, a collection of scientists from varied domains converged to rethink, among other things, what we now call Geographic Information Systems (GIS) (Narayan 2014; Alcaraz et al. 2016). This workshop was led by Howard Fisher to discuss improved computer mapping program for GIS which lead to development of SYMAP. Fisher wanted an improved spatial interpolation technique to augment his work on SYMAP. During a brain storming session one freshman, Donald Shepard (Shepard 1968), decided to overhaul the interpolation techniques in SYMAP. This resulted in formulation and implementation of the basic inverse distance weighting (IDW). The first scientific article on IDW which is known as Sheppard’s algorithm is published in his famous article from 1968 (Shepard 1968; Fisher et al. 1987).

Definition and Mathematical Expression

Inverse distance weighting (IDW) is a type of deterministic method for multivariate interpolation with a known scattered

set of points (Łukaszuk 2004). The assigned values to unknown points are calculated with a **weighted** average of the values available at the known points.

The mathematical equation of IDW of a phenomena “Z” whose sample magnitude at different known locations Z_i are collected prior. One has to compute the magnitude of the phenomena at a location “ Z_0 ” using the IDW formula given in equation 1.

$$Z_0 = \frac{\sum_{i=1}^n Z_i \frac{1}{D_i^p}}{\sum_{i=1}^n \frac{1}{D_i^p}} \quad (1)$$

where Z_i is magnitude of samples measured at known “n” locations ($i = 1, \dots, n$)

Z_0 is the unknown magnitude of the phenomena to be computed.

D_i^p is the p th power of the distance computed between the point of unknown sample magnitude with that of the known sample points.

Factors Governing IDW

Inverse distance weighting is the simplest spatial interpolation method (George and David 2008; Ozelkan et al. 2015). A neighborhood about the interpolated point is identified and a weighted average is taken of the observation values within this neighborhood. The weights are a decreasing function of distance. The user has the control over the mathematical form of the weighting function, the size of the neighborhood (expressed as a radius or a number of points), in addition to other options.

Weighting Function

The simplest weighting function in the IDW is inverse power “ $w(d) = 1/d^p$ ”. The value of p is specified by the user. The most common choice is $p = 2$. For $p = 1$, the interpolated function is “cone-like” in the vicinity of the data points, where it is not differentiable.

The power factor “ p ” decides the degree of influence of the phenomena. If ($p = 1$), then it is a simple inverse distance weight interpolation. If ($p = 2$), then it is inverse distance square weight. The value of “ p ” can be any value ≥ 1 depending on the model under consideration.

Shepard’s method (Shepard, 1968) is a variation on inverse power, with two different weighting functions using two separate neighborhoods. The default weighting function for Shepard’s method is an exponent of 2 in the inner

neighborhood and an exponent of 4 in the outer neighborhood. A generic mathematical representation of the Shepard’s method is given in equation 2. The form of the outer function is modified to preserve continuity at the boundary of the two neighborhoods.

$$Z_0 = \frac{\sum_{i=1}^{n-k} Z_i \frac{1}{D_i^2}}{\sum_{i=1}^{n-k} \frac{1}{D_i^2}} + \frac{\sum_{i=k}^n Z_i \frac{1}{D_i^4}}{\sum_{i=k}^n \frac{1}{D_i^4}} \quad (2)$$

Neighborhood Size

The neighborhood size determines how many points are included in the inverse distance weighting. The neighborhood size can be specified in terms of its radius (in km), the number of points, or a combination of the two. If a radius is specified, the user also can specify an override in terms of a minimum and/or maximum number of points. Invoking the override option will expand or contract the circle as needed. If the user specifies the number of points, as an override of a minimum and/or maximum radius can be included. It also is possible to specify an average radius “ R ” based upon a specified number of points. Again, there is an override to expand or contract the neighborhood to include a minimum and/or maximum number of points. In Shepard’s method, there are two circular neighborhoods; the inner neighborhood is taken to be one-third the radius of the outer radius.

Anisotropy Correction

In many instances, the observation points are not uniformly spaced about the interpolation points. Several points are in a particular direction and fewer in direction orthogonal to the dominant direction. This condition is known as anisotropic condition. This situation produces a spatial bias of the estimate, as the clustered points carry an artificially large weight. The anisotropy corrector permits the weighted average to downweight clustered points that are providing redundant information. The user selects this option by setting the anisotropy factor to a positive value. A value of 1 produces its full effects, while a value of 0 produces no correction. This correction factor is defined by computing the angle between every pair of observation points in the neighborhood, relative to the observation point.

Gradient Correction

A disadvantage of the inverse weighted distance functions is that the function is forced to have a maximum or minimum at the data points (or on a boundary of the study region). The gradient corrector permits a nonzero gradient at the observation points. The implementation is such that the interpolated value is the sum of two values.

One of the key governing factor of equation 1 is the value of number of samples “n” and their spatial alignment around the location of the point of interest. Many geometric approaches are in practice for selection of data points. In most of the software implementations a circular filter with a radius “R” around the point of interest has been in use to select the location of sample values. Some other implementations use a rectangular or square filter around the point of interest. If the values of the phenomena have to be computed for gridded locations from the value of sampled scatter points such as generation of a DEM (Digital Elevation Model) from a scatter point of surveyed heights, then a moving circular disk or rectangle is considered for computing the values for uniformly spaced grid locations.

How Inverse Distance Weighted Interpolation Works?

Inverse distance weighted (IDW) interpolation explicitly makes the assumption that things that are close to one another are more alike than those that are farther apart. To predict a value for any unmeasured location, IDW uses the measured values surrounding the prediction location. The measured values closest to the prediction location have more influence on the predicted value than those farther away. IDW assumes that each measured point has a local influence that diminishes with distance. It gives greater weights to points closest to the prediction location, and the weights diminish as a function of distance, hence the name inverse distance weighted. Weights assigned to data points are illustrated in the example 1.

The geometric shape and dimension of the search neighbor is an important factor in effectiveness of IDW. It is decided depending upon the spatial distribution of the sampled data locations and the characteristic of the sampled data. Some of the frequently used geometric search patterns employed in IDW are: (a) radial search with mean radius “R”, (b) spherical geometry with mean radius “R” for scattered data in 3D, (c) rectangular geometry with (Length(L) x Width(W)), (d) elliptic geometry with (semi major axis(a) and semi minor axis (b)), and (e) disk-like structure with inner radius “r” and outer radius “R” as depicted in Fig 1 a, b, c, d.

The geometric structure and its dimension decide the search neighbor for inclusion and exclusion of the values of sampled points for participating in computation of unknown value using IDW.

Once search neighbor is decided the next step for software implementation of IDW is to answer the question whether location (x_i, y_i) from among the sampled locations is within the sample neighbor? This question can be answered using computational geometric queries such as the following:

- (a) Point_inside_circle(X_i, Y_i, R)
- (b) Point_inside_ellipse(X_i, Y_i, a, b)
- (c) Point_inside_rectangle(X_i, Y_i, L, W)
- (d) Point_inside_Sphere (X_i, Y_i, R)

If the Point Inside Neighbor geometry returns TRUE, then the corresponding value V_i of (X_i, Y_i) is included for computation using IDW else it is discarded.

Further if the spatial extend of the physical phenomena is spread over a large extend marked by a bounding rectangle ($L \times W$), then the process of computing the values at different locations from the scattered data is obtained by repeatedly computing using the moving neighbor operator for the entire spatial domain.

To consolidate the concept of IDW, let us analyze a real-life example. One need to compute the depth of snow cover at a high slope and hazard location from among the values of snow precipitation surveyed from a set of known locations surrounding the location under question. This scenario is depicted in the Fig. 2. The field observations of five locations surrounding the point and their distance data is tabulated (Table 1). Using IDW the value of precipitation at the location in question is computed using equation 3. Also how the variation in the computed value is manifesting when computed using inverse square distance weight (ISDW) is analyzed in equation 4. One can see the variation in the computed value by IDW and ISDW. The variation is very small implicating the effectiveness and the resilience of the method.

IDW and ISDW are applied to above data separately to compute the precipitation of the snow in the location as depicted in Fig. 1.

$$34\left(\frac{1}{5}\right) + 42\left(\frac{1}{8}\right) + 17\left(\frac{1}{14}\right) + 52\left(\frac{1}{12}\right) + 27\left(\frac{1}{9}\right) = 20.597589 \quad (3)$$

$$34\left(\frac{1}{5^2}\right) + 42\left(\frac{1}{8^2}\right) + 17\left(\frac{1}{14^2}\right) + 52\left(\frac{1}{12^2}\right) + 27\left(\frac{1}{9^2}\right) = 2.797387 \quad (4)$$

The values computed at the location using IDW and ISDW are 26.0439 and 22.35799, respectively.

Therefore it is highly encouraged to use IDW or ISDW method judiciously to compute an estimate of the phenomena. Often the choice of the type and dimension of the search neighbor for filtering the spatial locations which can participate in computation of the unknown value using IDW is governed by many factors:

Inverse Distance Weight, Fig. 1 (a) Sampled locations within a circular neighbor, (b) elliptic neighbor for flow like phenomena, (c) circular disk neighbor, (d) spherical neighbor with undulated terrain

- (a) Whether the phenomena is random and scattered spatially.
- (b) Whether the phenomenon is directional like flow of air, water, etc.
- (c) Whether the phenomena are static or influenced more by local factors such as seizure from brain.

Depending on the type of physical phenomena and its spatial behavior the neighborhood geometry is selected.

- For random static phenomena the neighborhood geometry is circular with radius “R.”
- For air flow or fluid flow kind of phenomena it is recommended to use the elliptic structure.

- For chemical concentration or computation of value of precipitation of rain or snow circular neighborhood geometry should be more suitable.
- For computing the pressure and fault line in mines, slope and aspect of undulated terrain and geological exploration sphere like structure is more preferable.
- To find the exact location of brain from where seizure like EEG signals are emanating, spherical neighborhood geometry is more suitable.

The Behavior of Power Function

As mentioned above, weights are proportional to the inverse of the distance (between the data point and the location of prediction) raised to the power value p . As a result, as the

Inverse Distance Weight, Fig. 2 Snow precipitation measured at different Locations

Inverse Distance Weight, Table 1 Precipitation measured in known locations

Precipitation of snow in mm	Distance from the point of unknown value	Inverse of distance $1/D$	Square of inverse of distance $1/D^2$
34	5	$1/5 = 0.2$	$1/5^2 = 0.04$
42	8	$1/8 = 0.125$	$1/8^2 = 0.015625$
17	14	$1/14 = 0.071428$	$1/14^2 = 0.005102$
52	12	$1/12 = 0.083333$	$1/12^2 = 0.006944$
27	9	$1/9 = 0.111111$	$1/9^2 = 0.012345$

distance increases, the weights decrease rapidly. The rate at which the weight decrease is dependent on the value of “ p .” If $p = 0$, there is no decrease with distance, and because each weight D_i is the same, the prediction will be the mean of all the data values in the search neighborhood and IDW acts like an moving average interpolator. As p increases, the weights for distant points decrease rapidly. If the p value is very high, only the immediate surrounding points will influence the prediction. The nature of the weight becomes asymptotic with increase distance making the impact of the values of faraway locations less significant in the overall computation. This phenomena is depicted in the plot (Fig. 3).

In most of the geo-statistical analysis the value of p is chose to be 2, although there is no theoretical justification to prefer this value over others, and the effect of changing p should be investigated by previewing the output and examining the cross-validation statistics.

Inverse Distance Weight, Fig. 3 Relative weight of the known values decrease rapidly with increase of value of power factor “ p .” This is illustrated in the plot weight-distance with varying “ p ”

The Selection of Search Neighborhood

The philosophy of IDW modeling is that “things that are close to one another are more alike and related than those that are farther away.” As the locations get farther away, the measured values will have little relationship to the value of the prediction location. Also to speed us computations, one need to select a fixed set of known values from spatially close range and exclude the more distant points that will have little influence on the prediction. As a result, it is common practice to limit the number of measured values by specifying a search neighborhood. The shape of the neighborhood restricts how far and where to look for the measured values to be used in the prediction. Other neighborhood parameters restrict the locations that will be used within that shape. In the following image, five measured points (neighbors) will be used when predicting a value for the location without a measurement, the yellow point.

The shape of the neighborhood is influenced by the input data and the surface one is trying to create from the data. If there are no directional influences in the data, and observation points are equally distributed in all the directions then simple circular or spherical structure is preferred depending on the dimension of the data points. However, if there is a directional influence in the data, such as a prevailing wind, one may want to adjust for it by changing the shape of the search neighborhood to an ellipse with the major axis parallel to the direction of the flow of the wind. The adjustment for this directional influence is justified because one know that locations upwind from a prediction location are going to be more similar at remote distances than locations that are perpendicular to the wind but located closer to the prediction location.

Once a neighborhood shape has been specified, you can restrict which data locations within the shape should be used. One can define the maximum and minimum number of locations to use; also one can divide the neighborhood into sectors. If one divides the neighborhood into sectors, the maximum and minimum constraints will be applied to each sector.

The output surface generated using IDW is sensitive to clustering and the presence of outliers. IDW assumes that the phenomenon being modeled is driven by local variation, which can be captured (modeled) by defining an adequate search neighborhood. Since IDW does not provide prediction standard errors, justifying the use of this model may be problematic.

Applications of IDW

Given a set of known values such as elevation, rain in mm, pollution density or noise, there are different spatial interpolation techniques available to compute the value at unsampled location. IDW, Kriging, Voronoi tessellation, and moving average are some of the alternate tool. To estimate at points where you do not know its value, IDW uses spatial autocorrelation in its math. Closer values have more effect while farther away ones have less effect.

Application Considering Spatial Autocorrelation in 3D

Spatial interpolation is a main research method in 3D geological modeling, which has important impacts on 3D geological structure model accuracy. The inverse distance weighting (IDW) method is one of the most commonly used deterministic models, and its calculation accuracy is affected by two parameters: search radius and inverse-distance weight power value. Nevertheless, these two parameters are usually set by humans without scientific basis. To this end, we introduced the concept of “correlation distance” to analyze the correlations between geological borehole elevation values, and calculate the correlation distances for each stratum elevation. The correlation coefficient was defined as the ratio of correlation distance to the sampling interval, which determined the estimation point interpolation neighborhood. We analyzed the distance-decay relationship in the interpolation neighborhood to correct the weight power value. Sampling points were selected to validate the calculations. We concluded that each estimation point should be given a different weight power value according to the distribution of sampling points in the interpolated neighborhood. When the spatial variability was large, the improved IDW method performed better than the general IDW and ordinary kriging methods.

Spatial interpolation is a main research method in 3D geological modeling, which has important impacts on 3D geological structure model accuracy. The inverse distance weighting (IDW) method is one of the most commonly used deterministic models, and its calculation accuracy is affected by two parameters: search radius and inverse-distance weight power value. Nevertheless, these two parameters are usually set by humans without scientific basis. To this end, we introduced the concept of “correlation distance” to analyze the correlations between geological borehole elevation values,

and calculate the correlation distances for each stratum elevation. The correlation coefficient was defined as the ratio of correlation distance to the sampling interval, which determined the estimation point interpolation neighborhood. We analyzed the distance-decay relationship in the interpolation neighborhood to correct the weight power value. Sampling points were selected to validate the calculations. We concluded that each estimation point should be given a different weight power value according to the distribution of sampling points in the interpolated neighborhood. When the spatial variability was large, the improved IDW method performed better than the general IDW and ordinary kriging methods.

Syntax or Signature of API Implementing IDW

```
IDW(Surveyed_Data_Set_with_Location, Location_of_Unknown_Point, power_of_IDW, Dimension, z_field, search_neighborhood_geometry, cell_size, Output_Data_set)
```

To execute IDW

```
IDW(inPointFeatures, (Xi,Yi), zField, 2, 2, circular, 4, outDataSet)
```

Summary

IDW uses the measured values surrounding the prediction location to compute a value for any unsampled location, based on the assumption that things that are close to one another are more alike than those that are farther apart. It selects the neighborhood points from among the domain using a neighborhood policy which defines the geometry and search distance, or number of closest points. The power of the inverse distance decides the degree of influence of the phenomena. The search geometry and the search range are some of the decision one need to take before applying IDW. One need to choose higher power settings for more localized peaks and troughs, the directional behavior of the physical phenomena often plays a crucial role in choosing the shape of the filter, upper or lower bound of sample values to compute. Some of the key features of IDW are

- The predicted value is limited to the range of the values used to interpolate. Because IDW is a weighted distance average, the average cannot be greater than the highest or less than the lowest input. Therefore, it cannot create ridges or valleys if these extremes have not already been sampled.
- IDW can produce a bull's-eye effect around data locations.
- Unlike other interpolation methods such as Kriging, IDW does not make explicit assumptions about the statistical properties of the input data. IDW is often used when the

input data does not meet the statistical assumptions of more advanced interpolation methods.

- This method is well-suited to be used with very large input datasets.

The Inverse Distance Weighting interpolation method is as flexible and simple to program. But it is often the case that other interpolation techniques like kriging can help obtain a more robust model.

Definition

Inverse theory – The mathematical theory for deducing from observations the cause(s) that produce them.

Introduction

Inverse theory in general deals with deducing the cause from observations through intricate mathematical formulations. In geophysics, physical fields are recorded by various sensors located on the earth's surface, within boreholes or above the ground by airborne and satellite observations. These fields are

responses of physical property variations within the earth, and, thus, inversion theory is used to image the earth's structure in terms of physical property variations from the observations of physical fields (Tarantola 1987; Aster et al. 2019). Inverse theory is also used in other branches of geosciences to understand the geological processes, e.g., estimation of magma source composition from inversion of trace elements (Albarede 1983; McKenzie and O'Nions 1991). The subject of inverse theory and its application in geosciences is vast, and a lot of development has taken place in this field. In this entry, we provide a brief description of inverse theory to give a flavor of the subject.

In inversion approach, first a forward problem (► [Forward and Inverse Models](#)) is defined that relates model parameters $\mathbf{m}$ to observed responses $\mathbf{d}$ through a functional f as

$$\mathbf{d} = f(\mathbf{m}). \quad (1)$$

Here, the functional f contains information about the physics of the given problem. Since in geophysical studies, we aim at obtaining the unknown model parameters $\mathbf{m}$ from the observed responses $\mathbf{d}$, in the simplest form, ignoring all complications of noise in data and inadequacy of data, assuming that the exact inverse exists the inverse problem can be posed as

$$\mathbf{m} = f^{-1}(\mathbf{d}). \quad (2)$$

Inverse of a Discrete Problem

In general form, the model parameters are a continuous function of the spatial coordinate system and the functional is a continuous operator. This requires solving Eqs. 1 and 2 in the continuous domain. There are methods such as the Backus-Gilbert method that are used to solve such inverse problems. However, a generally followed practice is to convert the problem into the discrete domain such that $\mathbf{m} = \{m_1, m_2, \dots, m_N\}^T$ and $\mathbf{d} = \{d_1, d_2, \dots, d_M\}^T$, where M, N are number of observations and model parameters, respectively, and then express Eq. 1 in matrix form as

$$\mathbf{d} = \mathbf{F}\mathbf{m}. \quad (3)$$

In the ideal situation of noise-free data and full-rank matrix ($M = N = K$, where K is the rank of the matrix), inverse of Eq. 3 is

$$\mathbf{m} = \mathbf{F}^{-1}\mathbf{d}. \quad (4)$$

This is the desired exact solution of an inverse problem. However, geophysical inverse problems are mostly nonlinear, rank-deficient, and ill-conditioned, and in practice it is difficult to get the exact solution (Menke 1984; Tarantola 1987). Therefore, a generalized inverse of the problem is obtained by

imposing some other constraints. There are two main scenarios; (i) $M > N$, and (ii) $M < N$ assuming that the rank $K = \min(M, N)$. In the first case, the number of observations is more than the number of unknown model parameters. It is called a strictly overdetermined system (Gupta 2011) for which the error of misfit is

$$\mathbf{e} = \mathbf{d} - \mathbf{F}\hat{\mathbf{m}}, \quad (5a)$$

where $\hat{\mathbf{m}}$ is the estimated model parameter vector and is minimized in the least square sense, i.e., $\mathbf{e}^T \mathbf{e}$ is minimized that yields the best fit solution as

$$\hat{\mathbf{m}} = (\mathbf{F}^T \mathbf{F})^{-1} \mathbf{F}^T \mathbf{d}. \quad (5b)$$

In the second case, the number of observations is less than the number of unknown model parameters. It is called a strictly under-determined system. Here, the norm of the model parameter vector is minimized by minimizing $\mathbf{m}^T \mathbf{m}$ to yield the best fit solution as

$$\hat{\mathbf{m}} = \mathbf{F}^T (\mathbf{F} \mathbf{F}^T)^{-1} \mathbf{d}. \quad (6a)$$

There is another scenario when the rank of the matrix $K < \min(M, N)$. Inverse of an overdetermined system for such a case is obtained by minimizing an objective function that is a weighted sum of $\mathbf{e}^T \mathbf{e}$ and $\mathbf{m}^T \mathbf{m}$, i.e., minimizing $\mathbf{e}^T \mathbf{e} + \lambda^2 \mathbf{m}^T \mathbf{m}$, which yields

$$\hat{\mathbf{m}} = (\mathbf{F}^T \mathbf{F} + \lambda^2 \mathbf{I})^{-1} \mathbf{F}^T \mathbf{d}. \quad (6b)$$

Here, $\mathbf{I}$ is identity matrix and λ is the control parameter to assign relative weight to the data error and model norm, also known as the Marquardt parameter (Marquardt 1963). For an optimum value of λ , the L-curve is used which is constructed on a plane with axes as $\mathbf{e}^T \mathbf{e}$ and $\mathbf{m}^T \mathbf{m}$ for different values of λ . The value of λ is chosen to correspond to maximum curvature point of this curve. This is a simple case of regularization.

In case of noisy data, if the errors in data are given in terms of variances, then a weight matrix is introduced while minimizing errors as

$$\mathbf{e}^T \mathbf{C}_d^{-1} \mathbf{e}, \quad (7a)$$

where

$$\mathbf{C}_d = \begin{bmatrix} \sigma_{d1}^2 & 0 & \cdots & 0 & 0 \\ 0 & \sigma_{d2}^2 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & \ddots & 0 \\ 0 & 0 & \cdots & 0 & \sigma_{dN}^2 \end{bmatrix}. \quad (7b)$$

In this case the solution of the inverse problem is

$$\hat{\mathbf{m}} = (\mathbf{F}^T \mathbf{C}_d^{-1} \mathbf{F})^{-1} \mathbf{F}^T \mathbf{C}_d^{-1} \mathbf{d}. \quad (8)$$

Singular Value Decomposition

In the inversion approach described above, the generalized inverse is obtained by different matrix operations depending on the nature of the problem and the rank of the matrix. Singular value decomposition (SVD) (Singular Value Decomposition) does not require a priori information about the nature of the matrix and hence is very useful especially for inversion of singular or ill-conditioned matrices (Golub and Kahan 1965; Golub and Reinsch 1970). The technique was discovered independently by Beltrami in 1873 and Jordan in 1874 as a tool to solve square matrices and was extended to rectangular matrices by Eckart and Young in the 1930s (Stewart 1993; Manglik 2021). In SVD, a matrix $\mathbf{F}$ of dimension $M \times N$ and rank K is decomposed into data and parameter eigen matrices $\mathbf{U}(M \times K)$ and $\mathbf{V}(N \times K)$, respectively, and a diagonal matrix containing non-zero eigen values $\Sigma(K \times K)$ arranged in decreasing value of magnitude such that

$$\mathbf{F} = \mathbf{U} \Sigma \mathbf{V}^T. \quad (9)$$

An inverse of this matrix can be obtained as

$$\mathbf{F}^- = \mathbf{V} \Sigma^{-1} \mathbf{U}^T. \quad (10)$$

The data and parameter matrices satisfy the conditions $\mathbf{U}^T \mathbf{U} = \mathbf{V}^T \mathbf{V} = \mathbf{I}$ but $\mathbf{U} \mathbf{U}^T$ and $\mathbf{V} \mathbf{V}^T$ need not be the identity matrix for a geophysical problem. The first one is known as the information density matrix that provides information about the data sensing different model parameters, whereas the second one is called the parameter resolution matrix that is used to understand the resolution of model parameters. This matrix is very useful to find equivalence of model parameters. The SVD approach reduces the drudgery of computation and provides ease in interpretation.

Inverse of a Continuous Problem

Discrete inverse problem assumes that the model parameters are discrete in nature, i.e., the earth's structure is composed of discrete layers/cells each having constant values of physical properties. However, physical properties may vary continuously in spatial domain and observations made at discrete locations are a function of physical property variation in the entire domain. This leads to a situation where observed data are always less compared to the unknown model parameters (under-determined system). Backus and Gilbert (1967, 1968, 1970) developed an elegant approach to invert this continuous problem. This method tries to invert the parameters given by continuous functions. We have in this case

$$\int_0^1 F_i(x)m(x)dx = d_i, \text{ for the domain in the range, } 0 \leq x \leq 1, \quad (11)$$

where $m(x)$ represents continuous model parameter variation and $F_i(x)$ is a function describing the physics of the problem. The subscript i denotes the index of the data point ($i = 1, 2, \dots, N$). Here, we have finite set of data and wish to estimate the unknown function $m(x)$. To do this, we first express m at $x = x_0$ in terms of the Dirac delta function as

$$m(x_0) = \int_0^1 \delta(x - x_0)m(x)dx, \quad (12)$$

and assume that $m(x_0)$ is a linear combination of the data with weights a_i , ($i = 1, 2, \dots, N$), i.e.

$$\sum_{i=1}^N a_i d_i = m(x_0). \quad (13)$$

Substituting Eq. 11 into Eq. 13 gives

$$\sum_{i=1}^N a_i d_i = \sum_{i=1}^N a_i \int_0^1 F_i(x)m(x)dx = \int_0^1 \left\{ \sum_{i=1}^N a_i F_i \right\} m(x)dx. \quad (14)$$

Comparing Eq. 14 with Eq. 12, we get

$$\sum_{i=1}^N a_i F_i = \delta(x - x_0). \quad (15)$$

This is the ideal situation in which we get the exact solution of the model at $x = x_0$. However, this is mostly not possible and weights a_i are obtained such that $\sum_{i=1}^N a_i F_i$ is as close to the

Dirac delta function as possible and we get an estimate $\hat{m}(x_0)$ of the true model $m(x)$ around $x = x_0$. The spread of the function gives information about the resolution of the model. An example of application of the Backus-Gilbert method to magnetotelluric data can be found in Manglik and Moharir (1998).

Bayesian Inversion

In this inversion approach (► [Bayesian Inversion](#)), the model is considered as a random variable unlike the methods

described in previous sections that treat the model as deterministic. The model thus has a probability distribution and we invert for a posterior distribution of the model parameters from the known prior distribution for the model and the data. The posterior distribution of the model according to the Bayes theorem is expressed as

$$f_{M|d} = \frac{f_{D|m}f_M(m)}{f_D(d)}, \quad (16)$$

where $f_M(m)(f_D(d))$ is the probability density function (► [Probability Density Function](#)) for model (data) and $f_{M|d}(f_{D|m})$ is the conditional probability distribution of model given data (or data given model). This can be demonstrated for a normal distribution by considering that the model follows a Gaussian distribution so that the probability $f_M(m)$ is expressed as

$$f_M(m) \propto \exp \left[-\frac{1}{2} \left\{ (m - m_{\text{prior}})^T C_m^{-1} (m - m_{\text{prior}}) \right\} \right], \quad (17)$$

where m_{prior} and C_m are the mean of the prior distribution of the model and its covariance matrix. The conditional distribution of data given model is then

$$f_{D|m} \propto \exp \left[-\frac{1}{2} \left\{ (Fm - d)^T C_d^{-1} (Fm - d) \right\} \right], \quad (18)$$

where d represents observed data with C_d corresponding data covariance matrix. Using Bayes theorem, we can get model posterior conditional probability density function given data as

$$f_{M|d} \propto \exp \left[-\frac{1}{2} \left\{ (m - m_{\text{prior}})^T C_m^{-1} (m - m_{\text{prior}}) + (Fm - d)^T C_d^{-1} (Fm - d) \right\} \right]. \quad (19)$$

Equation 19 can be simplified to (Tarantola 1987)

$$f_{M|d} \propto \exp \left[-\frac{1}{2} (m - m_{\text{MAP}})^T C_{M'}^{-1} (m - m_{\text{MAP}}) \right], \quad (20)$$

where m_{MAP} is the maximum a posteriori model and modified covariance matrix $C_{M'}$ and is given by

$$C_{M'} = (F^T C_d^{-1} F + C_m^{-1})^{-1}. \quad (21)$$

The maximum a posteriori model m_{MAP} is obtained by minimizing the following expression

$$(m - m_{\text{prior}})^T C_m^{-1} (m - m_{\text{prior}}) + (Fm - d)^T C_d^{-1} (m - d). \quad (22)$$

Bayesian method is highly computationally intensive as a large number of random samples from probability distributions are generated.

Inversion of a Nonlinear Problem

Geophysical inverse problems are in general nonlinear in nature. The above discussed linear inverse theory for discrete systems is applied to nonlinear problem by quasi-linearizing the nonlinear problem through Taylor's series expansion. Here, the model is expanded around some initial model $\mathbf{m}_0$ assuming that the model perturbation $\delta\mathbf{m}$ is small

$$\mathbf{d} = f(\mathbf{m}) = f(\mathbf{m}_0 + \delta\mathbf{m}) \approx f(\mathbf{m}_0) + \mathbf{G}'\delta\mathbf{m} + \dots, \quad (23)$$

where

$$\mathbf{G}' = \left. \frac{\partial f}{\partial \mathbf{m}} \right|_{\mathbf{m}=\mathbf{m}_0}. \quad (24)$$

Ignoring second- and higher-order derivatives in Eq. 23, we get

$$\delta\mathbf{d} = \mathbf{d} - \mathbf{d}_0 = \mathbf{G}'\delta\mathbf{m}, \quad \mathbf{d}_0 = f(\mathbf{m}_0). \quad (25)$$

Thus, we get again a linear form of inverse problem

$$\delta\mathbf{d} = \mathbf{G}'\delta\mathbf{m}, \quad (26)$$

which is solved for perturbation in model parameters given perturbation in data. Once perturbation in model parameters is estimated, the model is updated and the process is repeated till the desired convergence is obtained. Thus, the solution is obtained iteratively.

The quasi-linearization approach tries to converge to a minimum closest to the chosen initial model $\mathbf{m}_0$. For a highly nonlinear problem having several minima, this approach might yield an incorrect solution corresponding to a local minimum. There are global optimization techniques such as simulated annealing and genetic algorithms (► [Genetic Algorithm](#)) that are used to circumvent the issue of local minima (► [Optimization Methods](#)). Further development has taken place in the form of application of artificial neural networks to construct model parameter space from observed geophysical data (► [Artificial Neural Network](#)). Recently, data-driven approaches of machine learning (► [Machine Learning and Geosciences](#)) and hybrid data-driven and physics-based approaches (► [Deep Learning](#)) have also made in-roads to

interpretation of geophysics data in terms meaningful models of the subsurface.

Geophysical Example

We demonstrate an application of the inverse theory in developing a joint inversion (JI) algorithm for interpretation of seismic and magnetotelluric geophysical data. These two methods sense different physical properties, namely, bulk and shear moduli, and Poisson's ratio through seismic velocities, and electrical resistivity, respectively, of the earth. JI algorithms allow inverting of such diverse and unrelated datasets together, under the assumption that the geometry of the causative structure is the same, to obtain an integrated model of the earth's structure. Here, we give the mathematical description in very brief. For the detailed formulation, one may refer to Manglik and Verma (1998) and Manglik et al. (2009) and for field application to Manglik et al. (2011).

In the forward problem of magnetotelluric method, apparent resistivity (ρ_a) and phase (ϕ_a) measured on the surface of the earth are linked to the resistivity distribution inside the earth in terms of surface impedance Z_1 as

$$\rho_a(\omega) = \frac{1}{|w|} Z_1^* Z_1, \quad \phi_a(\omega) = \tan^{-1} \frac{\text{Im}(Z)}{\text{Re}(Z)}, \quad (27)$$

where $w = \sqrt{-i\omega\mu}$, ω is the angular frequency, μ is the magnetic permeability of the medium, and “*” represents the complex conjugate. For a n -layered model (n^{th} layer begin the half-space), the impedance of the i^{th} layer is represented as

$$Z_i(\omega) = f(Z_{i+1}(\omega), \omega, \rho_i, h_i), \quad \text{with } Z_n(\omega) = w\sqrt{\rho_n}, \quad (28)$$

where ρ_i and h_i are the electrical resistivity and thickness, respectively, of the i^{th} layer. The partial derivatives of ρ_a and ϕ_a with respect to the unknown layer parameters ρ_i and h_i , needed to construct the matrix $\mathbf{G}'$ (Eq.24), can be obtained from Eqs. 27 and 28.

Seismic travel time modeling involves refraction and reflection travel times. For surface seismics, the time t_i^{rr} taken by head waves generated by a critically refracted wave at the i^{th} interface of an isotropic, horizontally layered earth, and recorded at an offset distance X can be expressed as

$$t_i^{\text{rr}} = f[X, v_k(k=1, \dots, i), h_k(k=1, \dots, i-1)], \quad (29)$$

where v_k is the seismic velocity of the k^{th} layer. Similarly, reflection travel time t_i^{rf} of a wave reflected from the i^{th}

interface and recorded at an offset distance x is related to the model parameters as

$$t_i^{rf} = f[R, v_k(k=1, \dots, i), h_k(k=1, \dots, i)]. \quad (30)$$

Here, R is called the ray parameter which is a nonlinear function of the offset distance and velocity and thickness of layers. The partial derivatives of these seismic observations with respect to the model parameters can be obtained from these equations.

Following the quasi-linearization approach (Eqs. 25 and 26), we can write a combined matrix for geometrical JI as (dropping δ for ease of writing expressions)

$$\begin{Bmatrix} d_\rho \\ d_\phi \\ d_{rr} \\ d_{rf} \end{Bmatrix} = \begin{bmatrix} G_\rho^\rho & G_\rho^h & 0 \\ G_\phi^\rho & G_\phi^h & 0 \\ 0 & G_{rr}^h & G_{rr}^v \\ 0 & G_{rf}^h & G_{rf}^v \end{bmatrix} \begin{Bmatrix} \rho \\ h \\ v \end{Bmatrix} \quad \text{or} \quad \mathbf{d} = \mathbf{Gm}. \quad (31)$$

In this matrix, the data column vector $\mathbf{d}$ has the array dimension ($m^a \times 1$), where m^a is the sum of all observations corresponding to the four datasets and the model parameter vector $\mathbf{m}$ has array dimension $(3n - 1)$ corresponding to a layered earth model with $(n - 1)$ layers overlying a half-space. Equation 31 is solved by SVD (Manglik 2021).

A field example of application of this method is discussed by Manglik et al. (2011) who jointly inverted coincident deep crustal seismic (DCS) and magnetotelluric (MT) data at one shot-point along the Kuppam-Palani geotransect in the southern Indian shield. The geotransect was covered by different geophysical methods to delineate the crustal structure of various tectonic blocks of the Archaean to the Neoproterozoic age separated by shear zones. The study delineated a four-layer crustal model with a mid-crustal low velocity layer beneath the entire profile (Reddy et al. 2003) which is also found to be electrically conductive (Harinarayana et al. 2003). Quantification of physical properties and thickness of such low seismic velocity and high electrical conductivity layers (LVCL) sandwiched between high velocity and resistive layers is a challenging task because of certain limitation of these methods. In seismics, the absence of refraction from the top of a LVCL and trapping of seismic energy within the layer severely limits interpretation of seismic data for reliable estimates of the thickness and seismic velocity of the LVCL. Similarly, electrical and electromagnetic methods of geophysical exploration suffer from the well-known problem of equivalence due to which different combinations of conductivity and thickness of a subsurface layer for a 1-D earth can

produce similar response. This leads to a range of acceptable models, all satisfying the minimum root mean square (RMS) error criterion.

Manglik et al. (2011) performed JI of seismic reflection and refraction travel times (SI) and MT apparent resistivity and phase data to test the efficacy of the JI approach (Manglik and Verma 1998) in reducing the problem of equivalence and providing better constrained model of the LVCL compared to the models obtained by inversion of individual datasets. Another advantage of the JI approach is that the features of the model sensed by at least one method can be accounted for in the model and, thus, can yield an improved model of the subsurface structure. For example, a near-surface layer needed to explain the MT data was ignored by the SI method. Similarly, the Moho (a major interface between the crust and the mantle) is a prominent reflector in the SI data but may remain transparent in the MT data. Using these additional details, Manglik et al. (2011) modified the four-layer model of Reddy et al. (2003) to a six-layer model by including a thin near-surface conducting layer and a lithospheric mantle layer below the crust and jointly inverted the SI and MT data. The results are shown in Fig. 1a, b. For comparison, the results obtained by inversion of individual datasets are also shown in the figure. The JI results reveal that the LVCL is about 5 km thicker in comparison to the MT model but it is approximately the same as obtained by the SI method. However, the results depend on the choice of the initial guess due to the equivalence problem. Therefore, it is important to check for the sensitivity of the model to the choice of the starting model.

A model appraisal was performed by Manglik et al. (2011) to test if JI can better constrain the range of acceptable models compared to the range of SI and MT models. This was done by a systematic scan of the model parameter space for the LVCL covering the chosen resistivity, thickness, and velocity range of 50–200 $\Omega\cdot\text{m}$, 4–20 km, and 4–7 km/s, respectively, and constructing the starting models (shown by open circles in Fig. 1c, d) from this model space for inversion. Individual SI and MT inversions and JI inversion were performed for each of these starting models. The final models obtained after inversion corresponding to all starting models are also shown in Fig. 1c, d by diamonds for MT/SI and stars for JI. All these models fall in a narrow zone of minimum RMS error, suggesting that the parameters of LVCL suffer from the problem of equivalence. Since the parameters of LVCL converge in a long narrow zone of minimum RMS error even with JI, a cursory look at Fig. 1c, d would suggest almost no improvement. However, an analysis of the normalized RMS errors of all the final models has revealed a pattern. Here, normalization is done in such a way that the model having largest RMS error has normalized error of 1 and that having least RMS error now has a normalized error of 0. The results (Fig. 1e–g) corresponding to MT (triangles), SI (stars), and JI (diamonds)

Inversion Theory, Fig. 1 (a and b) Seismic velocity and electrical resistivity models obtained by inversion of individual seismic reflection and refraction (SI) data and magnetotelluric apparent resistivity and phase (MT) data as well as their joint inversion (JI). A six-layer earth model was considered for inversion. Starting model for inversion is shown as IG. (c and d) Appraisal of the seismic velocity and electrical resistivity of the LVCL. Circles, diamonds, and stars represent initial value, final value by individual methods, and final value by JI,

respectively. (e–g) Normalized RMS error vs. resistivity (e), seismic velocity (f), and thickness (g) for various models used in (c and d). Models with less than 10% error (shaded region) are considered as acceptable models. Triangle, stars, and diamonds represent MT, SI, and JI solutions, respectively. [Reprinted/adapted by permission from Springer Nature: Springer Nature, Joint Inversion of Seismic and MT Data – An Example from Southern Granulite Terrain, India by A. Manglik, S.K. Verma, K. Sain et al. (2011)].

reveal a narrowing of the zone of acceptable models if one considers the models falling within 10 percent of the least normalized error (shaded region) as acceptable. It can be seen that SI models have more scatter in the range of acceptable models. The LVCL with seismic velocity and thickness in the range of 3.25–5.75 km/s and 5.5–12.8 km, respectively, can fit the observed data equally well. MT gives a better constrained model of the LVCL with resistivity and thickness in the range of 106–110 $\Omega\cdot\text{m}$ and 9.8 km, respectively. In contrast, JI models fall in the seismic velocity range of 5.0–5.8 km/s with the minimum at 5.4 km/s, resistivity in the range of 115–140 $\Omega\cdot\text{m}$ with minimum at 122 $\Omega\cdot\text{m}$, and thickness in the range of 10–13 km with the minimum at 11.5 km. These results indicate that JI gives a well-constrained model of the LVCL and reduces the ambiguity in its parameters.

Summary

Inverse theory has been applied to interpret diverse geophysical and geochemical data to image the earth's interior and understand the processes since its use in seismology by Backus and Gilbert (1968) and Tikhonov and Arsenin (1977). Problem is essentially reduced to solving a linear algebra problem. Current endeavor is to use more data-intensive techniques such as machine learning to reduce uncertainty in the solutions.

Inversion Theory in Geoscience

Shib Sankar Ganguli and V. P. Dimri

CSIR-National Geophysical Research Institute, Hyderabad, Telangana, India

Definition

Inverse problems are familiar to numerous disciplines of geosciences that relate physical properties characterizing a model, m , with its model parameters, m_i , to collected geoscientific observations, i.e., data, d . This demands a knowledge of the forward model competent in predicting geoscientific data for specific subsurface geological structures. The modeled data can be expressed as

$$d = G(m, m_i). \quad (1)$$

Here G is the forward modeling operator, which is a nonlinear operator in most geoscientific inverse problems. In practice, for an inverse method, a model of the feasible subsurface is assumed and the model response is computed, which is subsequently compared with the observed data. This procedure is repeated several times until a minimum difference between the model response and observations is obtained.

Inverse Theory with Essential Concepts

In any geoscientific inverse problem, the ultimate aim is to estimate the earth's physical properties from the surface or subsurface measurements, which have been experienced variation in properties of the earth element. Undeniably, inverse theory is also capable of deciphering the quality of the predicted model than just determining model parameters. It can assist in deciding which model parameters or which combinations of model parameters are the most appropriate

representatives of the earth's subsurface. Further, it can be also useful in analyzing the effect of noise on the stability of the solution. For all of these, it is essential to realize the theoretical response of an assumed earth model (i.e., simulation or forward problem), thereby establishing the mathematical relationship among discrete data and a continuously defined model. Generally speaking, a real geological scenario is approximated by considering a simple model, and relevant model parameters are inferred from the observed data. This is known as an inverse problem. Mathematically, it is also possible to formulate a forward problem as an inverse problem. The general forward and inverse problems can be expressed as:

Forward problem : model $\{ \text{model parameters, } m_i \} \rightarrow \text{data}.$

Inverse problem : data $\rightarrow \text{model } \{ \text{estimated model parameters, } m_i \}.$

Finding solutions to the geoscientific inverse problems has always been at the forefront of an active research area, and therefore methods such as direct inversion, linear and iterative inversions, and global optimization methods have been investigated methodically. Even though the forward problem can provide a unique solution, the inverse problem does not. Inverse problem has multiple solutions and hence a priori information becomes vital to obtain meaningful model parameters. In general, a priori information on the model parameters is characterized using a probabilistic point of view on model space. The model space is a hypothetical space with manifold space points, independent of any specific parametrization, each of which essentially signifies a plausible model of the system. Apart from the obvious goal of estimating a set of model parameters, it is equally important to estimate the formal uncertainties in the model parameters. The ultimate goal is, of course, to obtain a reasonable, valid, and acceptable solution to the inverse problem of interest. A comprehensive framework showing the real implementation of various inversion methods including the process workflow to infer earth physical properties is illustrated in Fig. 1. Each element of a typical geophysical inverse problem, central for obtaining a meaningful solution, is indicated by arrows (Fig. 1). It can be seen that the inversion process comprises inputs (e.g., geophysical data, the equations that consider governing physical laws, a priori information about the problem), implementation (e.g., forward simulation and the inversion approach), and evaluation (e.g., assessment of the model). During the implementation stage, it is ensured that the relevant components are properly defined so that a well-posed inverse problem is developed and is being solved mathematically. For an effective geophysical inversion, two abilities of the algorithm become important and these are:

(a) the ability to run a forward simulation and generate synthetic data given a physical model and (b) the ability to appraise the model performance and update the model until the misfit function is optimized (Fig. 1). Regularization plays a critical role in the evaluation of the model's performance so that a suitable model is developed that is in good agreement with a priori information and assumed statistical distributions. Numerically, the inversion problem will be solved through optimization to obtain the unknown earth parameters. During optimization, often we need to alter the model regularization or change the aspects of numerical computations until the final model is accepted based on how well the model fits the observed data with less uncertainty. For more details, several excellent textbooks on the geophysical inverse theory are accessible, and interested readers are referred to Tarantola (1987), Menke (2012), Richter (2020), and others.

In any geoscientific inverse problem, the following significant issues related to the problem of finding solutions remain valid:

1. Does the solution exist for the problem?
2. If yes, then is it unique?
3. Is it stable and robust?

The existence of solution ($\{m, m_i\} = G^{-1}d$) is usually related to the mathematical design of the inverse problem. It is important to note that, from a physical perspective dealing with geological structures, a certain solution to the problem is anticipated. However, it may be also possible that the mathematical perspective could not provide an adequate numerical model that would fit the observations (data). There is an infinite possibility of models of a given subsurface geological condition that could match the data. In general, material properties within the subsurface are characterized by continuous functions, and the inversion method attempts to derive these functions from the set of observations of a finite number of data points. This leads to the problem of nonuniqueness in results. Let us assume two different models, m_1 and m_2 with two different sources, S_1 and S_2 that generate the same data d , then it is difficult to distinguish these two models from the given set of observations, and the solution will be nonunique. A solution will be considered as unique if these two diverse models, m_1 and m_2 , will produce two dissimilar data sets, d_1 and d_2 ($d_1 \neq d_2$).

By and large, geophysical data are invariably contaminated with some amount of noise. Hence, the last problem dealing with the stability and robustness of the solution is pivotal in geophysical inversion. Stability specifies how minor errors obtained during observations spread into the model and robustness deals with the magnitude of insensitivity concerning a small number of large errors within the data.

Inversion Theory in Geoscience, Fig. 1 A comprehensive framework of geophysical inversion including inputs, implementation of algorithms, evaluation, and interpretation (Cockett et al. 2015).

A stable and robust solution is insensitive to small errors in the data. An inverse problem is said to be *ill-posed* if the solution is unstable and nonunique; however, such inverse problems can result in physically and/or mathematically

meaningful solutions if regularization techniques are applied to them (Tikhonov and Arsenin 1977; Dimri 1992).

In practice, inversion methods are categorized into two broad classes: direct inversion methods and model-based

inversion methods. For the sake of completeness, these two are discussed in the subsequent parts of this chapter.

Direct Inversion Methods

In the case of direct inversion, the model is derived directly from the data without any assumptions on the model parameter values. These types of inversion schemes are implemented by a mathematical operator, which is derived based on the governing physics of the forward problem and subsequently applied to the data directly. The layer-stripping method is one of the most familiar direct inversion methods used in seismology to infer the medium properties of 1D acoustic or elastic medium. This is founded on the forward problem dealing with the reflectivity concept accounting for the plane wave response of the medium at individual frequency. A synthetic seismogram can be generated by combining the responses of all the plane waves for a layered earth model and applying inverse Fourier transform to the same. In practice, seismic data is transformed from the travel-time domain to the intercept time ray parameter domain and then the effects of each layer are pulled out by means of downward continuation during the estimation of layer properties. The foundation of this technique is on the assumption that seismic data is collected in noise-free conditions and is essentially in the broadband range. Such a scenario is difficult in a real field study, therefore, information about the frequency content needs to be supplied self-sufficiently in order to obtain stable model parameters. Apart from this, another direct inversion method is Born inversion, which is based on the inverse scattering approach (popular as Born theory). The important limitation of the layer-stripping algorithm is relaxed in this case by considering the earth to be varied in 2D or 3D. This is treated as a concomitant high-priority approach and is of interest since the Born theory implicitly contains migration with a proper band-limited layer property estimate. That said, the algorithm can estimate the precise time and amplitudes of all internal multiples independent of whether the medium is acoustic or elastic, deemed to be useful in deciphering subsurface structures. One of the major limitations of direct inversion methods is that these algorithms are sensitive to noise and often it becomes problematic for the operator to infer meaningful information from the data contaminated with noise. Such issues can be controlled, to some extent, in a model-based inversion approach where uncertainties associated with data are mostly addressed.

Model-Based Inversion Methods

A model-based inversion algorithm employs a forward model to compute synthetic data, which is then compared with the

observed data, unlike the direct inversion approach. The process of generating synthetic data is repeated until a proper match between the computed and observed is obtained. If the match between observed and computed is acceptable with minimum error, the model is accepted as the solution to the inverse problem. This repeated process, in essence, is viewed as an optimization problem in which the derived model elucidates the set of observations in a much more effective sense. Based on the approach of a search for an optimum model, optimization methods differ. The simplest and best-understood optimization method is one that can be represented with an explicit linear equation, which laid the foundation of linear discrete inverse theory. The discrete inverse theory can be expressed as

$$d_k = \sum_{l=1}^M G_{kl} m_l. \quad (2)$$

Whereas the continuous inverse theory considers discrete data, in which a continuous model function can be represented as

$$d_k = \int G_k(x) m(x) dx. \quad (3)$$

As stated earlier, the observed data in inverse problems are always discrete. Hence, a discrete inverse problem is taken into consideration by approximating the data and model as vectors, which are represented in the following forms

$$\begin{aligned} d &= [d_1, d_2, d_3, \dots, d_{ND}]^T, \text{ and } m \\ &= [m(x_1), m(x_2), m(x_3), \dots, m(x_{NM})]^T, \end{aligned}$$

where ND is the total number of data points, NM is the total number of model parameters, and T defines the transpose of a matrix.

Generally speaking, the solution to the linear inverse problem is based on measures of the size or length of the misfit (objective function) between the observed and calculated data. The length, namely Euclidean length, of the prediction error, is usually defined by “norm” and can be represented by the sum of the absolute values of the components of the error vector. Consequently, the best model is then the one that culminates in the smallest overall error (e_k):

$$e_k = d_k^{\text{obs}} - d_k^{\text{pre}} = d_k^{\text{obs}} - G(m). \quad (4)$$

The most commonly used norms are characterized by L_n norm (Menke 1984), where n is the power, takes the following form

$$L_1 \text{ norm : } \|e\|_1 = \left[\sum_{k=1}^{ND} |e_k|^1 \right], \quad (5)$$

$$L_2 \text{ norm : } \|e\|_2 = \left[\sum_{k=1}^{ND} |e_k|^2 \right]^{\frac{1}{2}}, \quad (6)$$

$$L_n \text{ norm : } \|e\|_n = \left[\sum_{k=1}^{ND} |e_k|^n \right]^{\frac{1}{n}}, \text{ where } n = 0, 1, 2, \dots, \infty \quad (7)$$

or, in vector notation, it can be expressed as:

$$L_n \text{ norm : } \|e\|_n = \left[(d_k^{\text{obs}} - G(m))^T (d_k^{\text{obs}} - G(m)) \right]^{\frac{1}{n}}. \quad (8)$$

Different norms offer different weights to outliers. Comparatively, the higher norms provide more weights to large elements of the misfit between the observed and predicted data. To understand how the concept of measure of length can be pertinent to the solution of an inverse problem, let us consider a simple problem of fitting data to (m, d) pairs with a single outlier, as depicted in Fig. 2. We wish to obtain a norm that leads to a straight line that passes across the set of data points (m, d) so that the sum of the squared residuals (errors) is minimal. Figure 2 demonstrates that three lines are fitting the data points corresponding to L_1 , L_2 , and L_∞ norms. As expected, the L_1 norm is least sensitive to the presence of outlier, whereas the L_∞ norm finds the curve which minimizes the largest single error between the observed and

predicted values. Also, the latter is strongly influenced by the outlier and is unable to eradicate the error (residual) since that may establish a large error elsewhere. Hence, the choice of norm determines how the total error can be quantified, wherein the norm is preferred to signify the nature of noise or scatter in the observed data.

Among the various available norms, the L_2 norm is the most widely applied norm in geophysical inverse problems. The preference of L_2 norm over L_1 norm is because the former weights the data outliers that lie nowhere near the average trend (Fig. 2) and obeys Gaussian statistics. Application of other kinds of norms, e.g., L_1 norm, has lately received attention in geophysical inversion (Wang et al. 2020). Generally speaking, a lower order norm is preferred for reliable estimates if the data are likely to be dispersed broadly about the average trend. A comparative analysis of these two norms is summarized in Table 1. It is evident that L_1 norm is more robust as compared to L_2 norm since the former is insensitive to a small number of big errors (outlier) in the data. This characteristic, in principle, gave new impetus to Huber (1964) to introduce the theory of robust estimation. Some interesting pieces of literature for more details about robust estimation are Hampel (1968) and Wilcox (2011).

Based on the search method to obtain the optimal solution, the model-based inversion can be classified into four categories, as discussed below.

Linear Inversion Methods

As the name suggests, these types of inversion techniques presume that data and models have a linear relationship. These methods have been implemented using linear algebra

Inversion Theory in

Geoscience, Fig. 2 Fitting a straight line to (m, d) data sets where the measured error is represented by L_1 , L_2 , and L_∞ norms (after Menke 1984). Note the L_1 norm offers a minimum weight to the outlier

Inversion Theory in Geoscience, Table 1 Summary of comparative analysis of using L_1 and L_2 norms

Features	L_1 norm	L_2 norm
<i>Quality aspect</i>	Robust	Not very robust
<i>Output</i>	Sparse	Non-sparse
<i>Accuracy</i>	Better	Good
<i>Computational time</i>	More	Less
<i>Programming used</i>	Linear	Least squares

in many geophysical applications for the past several decades. Of course, these algorithms innately demand certain conditions to establish a linear relationship between data and model. For instance, in Zoeppritz equations, the reflection coefficients are nonlinearly related to the P-wave velocity (V_p), S-wave velocity (V_s), and density. In exploration seismology, the Zoeppritz equations are a set of equations that define the segregation of incident seismic energy at a planar interface, typically a boundary between two layers of rock. These equations become helpful in the detection of petroleum reservoirs, especially during the investigation of the governing factors affecting the amplitude of the plane waves when the angle of incidence is altered. However, these equations are essentially nonlinear and to solve this problem, researchers have derived a linearized form of these equations, which are valid for small angles of reflection. An alternative way to establish a linear relation is to consider a linear relationship among perturbations in data and that in the model. This linear relationship remains valid as long as the perturbation in the model from the initial model is small. The linear relationship between the data perturbation and model perturbation can be accomplished by assuming that due to a small perturbation δm to a reference model m_0 , the model is affected by the forward modeling operator (G) in a way that results in the observed data in the following form

$$d_{\text{obs}} = G(m_0 + \delta m), \text{ and } d_{\text{syn}} = G(m_0).$$

To obtain the linearize relation, we implemented Taylor's series expansion about some initial guess of m_0 as

$$G(m_0 + \delta m) = G(m_0) + \left. \frac{\partial G(m_0)}{\partial m} \right|_{m=m_0} \Delta m + \dots \quad (9)$$

Now neglecting the second- and higher-order terms, we get

$$d_{\text{obs}} = d_{\text{syn}} + \left. \frac{\partial G(m_0)}{\partial m} \right|_{m=m_0} \Delta m \text{ or } \Delta d = G_0 \Delta m, \quad (10)$$

where Δd is the data misfit, i.e., vector difference between the observed data and modeled data, and G_0 is the sensitivity matrix comprises partial derivatives of synthetic data concerning model parameters. After knowing G , and that its

inverse operator exists, we can easily solve for the model vector by implementing the inverse operator for G , i.e., G^{-1} to the data vector. Also, note that it is possible to get an update to the model perturbation by merely applying G_0^{-1} to the data residual vector.

The solution to the linear inverse problem ($d = Gm$) is straightforward and can be derived from the widely used least-square inverse method, as given below:

$$G^T d = (G^T G) m. \quad (11a)$$

Now, assuming that $(G^T G)^{-1}$ exists, we can obtain the model parameter estimates in the form of

$$m^{\text{est}} = (G^T G)^{-1} G^T d. \quad (11b)$$

Thus, from knowledge of the matrix $(G^T G)^{-1} G^T$, which is known as Moore-Penrose generalized inverse (Dimri 1992), and its operation on the data, we can infer about the model parameters of interest. In order to get one unique solution, one of the important criteria is that there are as many systems of equations as the number of unknown model parameters. Such a system involves a situation that the data has enough information on all the model parameters, which means the number of data points is equal to the number of model parameters to be determined, i.e., $ND = NM$. This is a case of an *even-determined* problem. In a system, where $NM > ND$, i.e., the model parameters are more as compared to the observed data, then it is known as an *under-determined* problem. The system of equations, in this case, can determine uniquely some of the model parameters and fails to offer adequate relevant information to estimate uniquely all the model parameters. Generally speaking, this would typically be the situation with almost every geoscientific inverse problem, in which we strive to infer continuous (mainly infinite) earth model parameters from a finite set of observed data. Often, the problem is reduced to an *even-determined* or *over-determined* ($ND > NM$) problem by simply splitting the earth model into a set of discrete layers in lieu of solving for the earth parameters as a continuous function of spatial coordinates. Another possibility of a case may occur in practice, in which the observed data may encompass complete information on several model parameters and not a bit on the others. Such a case is referred to as a *mixed-determined* problem, which arises in seismic tomography studies, there may be one block that receives several rays while other blocks are devoid of a single ray coverage (completely undetermined).

For an *under-determined* problem, the pseudo inverse (Moore-Penrose generalized inverse) can be written as:

$$m^{\text{est}} = G^T (G^T G)^{-1} d, \quad (11c)$$

and for a completely *over-determined* problem, the model parameters can be obtained by the weighted least square solution, as given by

$$\mathbf{m}^{\text{est}} = (\mathbf{G}^T \mathbf{W}_e \mathbf{G})^{-1} \mathbf{G}^T \mathbf{W}_e \mathbf{d}, \quad (11d)$$

where the matrix $\mathbf{W}_e$ is known as the weighting factor, which denotes the relative influence of each error on the total prediction error.

It is important to note that the matrix $\mathbf{G}^T \mathbf{G}$ can occasionally be singular or nearly singular, so the inversion of the matrix is not possible or calculated imprecisely. The damped least squares method is proposed as a solution. For this, the solution to the inverse problem can be represented as

$$\mathbf{m}^{\text{est}} = (\mathbf{G}^T \mathbf{G} + \lambda \mathbf{I})^{-1} \mathbf{G}^T \mathbf{d}, \quad (11e)$$

where λ and $\mathbf{I}$ denote the damping parameter and identity matrix, respectively. The damping parameter (λ) plays a major role in preventing the inversion from blowing-off by increasing the magnitude of eigenvalues of the matrix (Dimri 1992; Menke 2012; Ganguli et al. 2016). The damped least square method is analogous to the regularization method (e.g., Tikhonov regularization) that minimizes the objective function (misfit) in a least square manner and ensures the smoothness of the model parameters. In practice, λ regulates the smoothness of the model which is attained in an iterative sense. For a detailed study on regularization techniques, damped least squares, weighted least squares, and the Backus-Gilbert method for ill-posed inverse problems, see Menke (1984) and Dimri (1992).

For the solution of the inverse problem of type $\mathbf{d} = \mathbf{G}\mathbf{m}$, there may be a situation that the least square inversion begets numerical inaccuracies while generating the matrix $\mathbf{G}^T \mathbf{G}$. In such a scenario, it is prudent to obtain a straightforward solution, i.e., $\mathbf{m}^{\text{est}} = \mathbf{G}^{-1} \mathbf{d}$. In general, it is not feasible to determine $\mathbf{G}^{-1}$ employing standard approaches, since $\mathbf{G}$ is not a square matrix in most of the geoscientific cases. To overcome this, singular value decomposition (SVD) of the matrix $\mathbf{G}$ can be performed to compute the pseudo inverse. SVD is an extremely effective method for factorizing the matrix $\mathbf{G}$ ($\text{ND} \times \text{NM}$) into orthogonal matrices in the following manner

$$\mathbf{G} = \mathbf{U} \mathbf{S} \mathbf{V}^T, \quad (12)$$

where $\mathbf{U}$ ($\text{ND} \times \text{ND}$) is the left orthogonal matrix, is $\mathbf{V}$ ($\text{NM} \times \text{NM}$) the right orthogonal matrix, and $\mathbf{S}$ is a singular value matrix consisting of singular values as diagonal elements in decreasing order, respectively. If $\mathbf{G}$ matrix is singular, then some of the elements in $\mathbf{S}$ will also be zero. Further, these two eigenvector matrices, i.e., $\mathbf{U}$ and $\mathbf{V}$ may be each divided into two submatrices $\mathbf{V} = [\mathbf{V}_p \mid \mathbf{V}_0]$, and $\mathbf{U} = [\mathbf{U}_p \mid \mathbf{U}_0]$, in which $\mathbf{V}_p$ and $\mathbf{U}_p$ are allied with singular values $\mathbf{S}_i \neq 0$ and

$\mathbf{V}_0$ and $\mathbf{U}_0$ are allied with the singular values $\mathbf{S}_i = 0$. The $\mathbf{V}_0$ and $\mathbf{U}_0$ vector spaces are known as “null spaces” because these are essentially the blind spots devoid of illumination by the operator $\mathbf{G}$. To cite some examples, the null space in seismic deconvolution corresponds to the frequencies that lie in the range outward of the estimated wavelet bandwidth. In crosswell seismic tomography, it primarily resembles a rapid change in horizontal velocity. In the presence of null space, the $\mathbf{G}$ matrix can be rewritten as

$$\mathbf{G} = [\mathbf{U}_p \mid \mathbf{U}_0] \begin{bmatrix} \mathbf{S}_p & 0 \\ 0 & 0 \end{bmatrix} [\mathbf{V}_p \mid \mathbf{V}_0]^T. \quad (13)$$

The uniqueness of the solution can be explained by $\mathbf{V}_p$ and $\mathbf{V}_0$ while the existence of the solution is attributed to the vector spaces $\mathbf{U}_p$ and $\mathbf{U}_0$. Therefore, we can write

$$\mathbf{G} = \mathbf{U}_p \mathbf{S}_p \mathbf{V}_p^T \text{ and } \mathbf{G}^{-1} = \mathbf{V}_p \mathbf{S}_p^{-1} \mathbf{U}_p^T.$$

Finally, we have the estimated model parameters as

$$\mathbf{m}^{\text{est}} = \mathbf{G}^{-1} \mathbf{d} (= \mathbf{G}\mathbf{m}) = \mathbf{V}_p \mathbf{S}_p^{-1} \mathbf{U}_p^T \mathbf{U}_p \mathbf{S}_p \mathbf{V}_p^T \mathbf{m} = [\mathbf{V}_p \mathbf{V}_p^T] \mathbf{m} = \mathbf{R}\mathbf{m}, \quad (14)$$

where $\mathbf{R} = \mathbf{V}_p \mathbf{V}_p^T$ is the model resolution matrix. If this matrix is an identity matrix ($\mathbf{R} = \mathbf{I}$), the solution is unique and the resolution is perfect. Otherwise, the resolution is not good with the estimated model parameters being some weighted averages of the true model parameters. Likewise, we can also write

$$\mathbf{d}^{\text{est}} = \mathbf{G}\mathbf{m}^{\text{est}} = [\mathbf{U}_p \mathbf{U}_p^T] \mathbf{d} = \mathbf{N}\mathbf{d}. \quad (15)$$

Here $\mathbf{N} = \mathbf{U}_p \mathbf{U}_p^T$ is called data resolution matrix, which measures the capability of the inverse operator to uniquely estimate the synthetic data. If $\mathbf{N} = \mathbf{I}$, the modeled data will be precisely similar to the observed data.

Iterative Linear Inversion Methods

We have now seen that the solution of the inverse problem of the type $\mathbf{d} = \mathbf{G}\mathbf{m}$ can be straightforwardly obtained by the method of least squares or the SVD method. However, such linear methods do not offer a solution if the linearity relation is not valid, especially for quasi-linear problems. These types of problems are solved by the iterative linear methods (also known as calculus-based methods), in which the minimum of the error function can be achieved iteratively by consecutive linear guesstimates at individual iteration, and refined successively until the stopping criterion is satisfied (Sen and Stoffa 1995). Most of the iterative methods do not necessitate the matrix to be explicitly well-defined. This inversion scheme updates the reference model (or a priori model) to

compute a new model and the difference between observed and synthetic data (Δd) is measured to evaluate the model performance. The process is repeated until the data misfit achieves its minimum and the relevant equation for the method is given below (Sen and Stoffa 1995):

$$m_{i+1} = m_i + G^{-1}[d_{\text{obs}} - G(m_i)], \quad (16)$$

where $G(m_i)$ generates the synthetic data for a model m_i to match iteratively the observed data, d_{obs} . This inversion method is reasonably sensitive to the initial model guess, therefore, among several minima, it prefers to choose the minimum of the error function adjacent to the starting model. In order to avoid the uncertainties due to data and prior models, both the data and model can be represented by random variables and the inversion can be solved in the context of probability theory.

Grid Search Method

This method entails a methodical search through each point (every possible) in model space to select the solution with the smallest error. For many geophysical inverse problems, it is a trying task to find “every possible” solution while computing the synthetic data for large model space. Yet a large set of trial solutions can be drawn from a regular grid in the model space. This method is most practical for problems where the total number of model parameters (NM) is small (trial solutions (L) can be proportional to L^{NM} , where the grid is M-dimensional) and the solution falls within a certain range of values which may be utilized to describe the limits of the grid. In general, several approximations are invoked to estimate the model parameters when the inputs are inadequate to use the grid search algorithm. Some applications of the grid search method to infer seismic parameters can be found in Koesoemadinata and McMechan (2003), Lodge and Helffrich (2009), and others.

Monte Carlo Method

The Monte Carlo method (MC) is an amendment of the grid search method in which the trial solutions are obtained, self-sufficiently of earlier ones, after some small and finite number of trials by random sampling of the model space. This involves a completely blind search of the model space, hence computationally expensive. In this method, theoretical values are computed based on each model parameter varying within a preset search interval (say $m_i^{\text{min}} \leq m_i \leq m_i^{\text{max}}$) and subsequently compared with the observed data. Afterward, a random number, say R_n , is sampled from a uniform distribution, $U [0,1]$, and is subsequently mapped into a model parameter. The new model parameter can be obtained by

$$m_i^{\text{new}} = m_i^{\text{min}} + R_n(m_i^{\text{max}} - m_i^{\text{min}}). \quad (17)$$

The latest model parameter is thus produced by random perturbation of a definite number of model parameters in the model vector. Model response is analyzed for the new model and compared with the observed data. If the difference between the observed data and modeled data is less than the previously accepted solution, the model is accepted. Otherwise, the model is rejected and the search continues several times until convergence is met. The most popular convergence criterion, in this case, is the total number of accepted models. With the advent of computational efficiency, millions of models can be attempted to obtain a suitable solution. One of the well-known applications of the MC algorithm in geophysics is to the inversion of seismic body wave travel times generating five million earth models with the data comprising 97 eigenperiods of free oscillations, travel times of P and S waves, and mass and moment of inertia of the earth (Press 1968). Finally, out of five million models, only six models met all the constraints. Through this work, Press (1968) addressed for the first time the problem of uniqueness through direct samples drawn from the model space.

There are, however, always two important issues with the MC method that need to be pondered and these are: (a) how to know whether one has tested sufficient models that represent the observations properly? and (b) how the successful models can be utilized to estimate the uncertainty in the estimation?

To make this method to be more practical in use, search space can be compacted, in fact, it can be defined through a pdf (preferably Gaussian with small variance) instead of a uniform distribution. It is desirable to devise random search-based algorithms that can sample a large portion of the model space more efficiently considering randomly selected several error functions. Due to the large degree of randomness, we can expect unbiased solutions. Also, it is equally important to avoid getting trapped in a local minimum of the error function. These types of issues can be well addressed by the directed Monte Carlo methods, e.g., simulated annealing and genetic algorithms. These two methods utilize random sampling to guide their search for models and results in a global minimum of the misfit function amidst several local minima, unlike the pure MC method. Both methods are suitable for large-scale geoscientific problems. Numerous pieces of literature are available that discuss the applications of MC methods and directed MC methods to solve various geoscientific problems (Sambridge and Drij koningen 1992; Sen and Stoffa 1995; Beaty et al. 2002) and many others.

Applications of Inverse Theory

Seismic Inversion to Detect Thin Layers

As an application of inverse theory in geophysics, we will provide here an example of a basis pursuit seismic inversion to detect the stratigraphic layer boundaries, especially

resolving thin layers, beneficial for reservoir characterization. Hydrocarbon exploration and development studies demand proper identification of layer boundaries and thin beds (mainly interbedded) in seismic. Although challenging, thin-bed imaging aids to develop a suitable petrophysical model that is more representative of the reservoir. Given the dominant frequency content of seismic, delineation of a bed with only a few meters thickness is still a burdensome job. Seismic inversion based on the least squares method involving Tikhonov regularization often fails to provide focused transitions between the adjacent layers. The basis pursuit inversion (BPI) algorithm based on L_1 norm optimization method can be formulated to obtain a more reliable detection of sharp boundaries between thin layers. The inverse problem is to infer the physical properties such as velocity (both V_p and V_s) and density of the stratigraphic layers from the amplitude variation with angle (AVA) seismic data. The initial model for prestack seismic data can be built in a similar way as performed in poststack case through interpolation and extrapolation of the well-log derived V_p , V_s , and density values. The BPI algorithm defines the objection function that comprises L_2 norm of the data misfit function and L_1 norm of the solution, and these functions are minimized concurrently to attain the final solution (Zhang et al. 2013). The objective function in the BPI method takes the following form

$$\min[\|d - G_w m_w\|_2 + \lambda \|m_w\|_1]. \quad (18)$$

Initially, a set of angle-dependent wavelets were identified through the calibration of individual angle datum with well log reflectivity, as a substitute for constant wavelets. The wavelet kernel matrix for the respective angle data was developed exploiting each wavelet having a length of 200 milliseconds (ms). The derivation of the density was ignored here since the maximum angle of investigation is only 20° , which is not suitable for inferring density. After testing the BPI algorithm in one well location, it was subsequently applied to a real field 2D seismic profile. The well log velocities are blocky filtered by a 10 ms window that essentially replaces the entire values within this specific window into the mean value. The inverted velocities were found to be in good agreement with the well log measured velocities, and the bed boundaries were well resolved in the seismic (Zhang et al. 2013). This also stands valid when 1D velocities derived from the well log, BPI method, and conventional method were compared.

For a proper comparison, the blocky filtered well log velocities were adapted because the well log contains high frequencies, and it is not advisable to compare the unfiltered well data with the inverted results. As a whole, the BPI algorithm could delineate the bed boundaries exceptionally well as compared to the conventional approach, offering valuable information for quantitative interpretation of elastic

properties. Of course, some discrepancies between the well log measured velocities and inversion results were detected; however, the BPI inverted results could follow the similar trend adopted by the conventional method. The BPI algorithm includes a wedge dictionary that supports an improved resolution of the single as well as double thin beds (interbedded layers) potential for hydrocarbon exploration. To get more insights on the BPI method and its detailed application for reservoir characterization, readers are referred to Zhang et al. (2013).

SVD Gravity Inversion to Identify Geological Structures

The second application of inverse theory in geoscience is presented here as SVD gravity inversion to decipher geological structures. The Bouguer gravity anomaly was analyzed in terms of eigenimages using SVD inversion. In practice, SVD decomposes the matrix G into a sequence of eigenimages, which appeared to be suitable for the separation of signal from background noise. In consonance with the nonlinear theory, singular geological processes are those which entail anomalous aggregates of energy release or accumulation within a restricted range of space or time. Any such anomalous energy aggregates due to geological features may be captured in a few particular eigenimages. Thus, to characterize the geological structure's potential for hydrocarbon or mineral prospects, it is significant to delineate those specific eigenimages employing the SVD inversion method. The SVD inferred singular values possess a unique feature of signifying diverse weighting coefficients of eigenimages. The SVD of the matrix G can be expressed as (Ganguli and Dimri 2013):

$$G = \sum_{k=1}^l \sigma_k U_k V_k^T. \quad (19)$$

According to the above equation, the G matrix can be reconstructed using the sequence of eigenimages. Note that the signal (i.e., Bouguer anomaly) can be suitably reconstructed from only those few eigenimages whose eigenvalues are not zero. In order to know which eigenimages will contribute more to the Bouguer anomaly reconstruction, the following equation can be considered:

$$P_k = \sigma_k^2 / \sum_{j=1}^l \sigma_j^2 = \lambda_k / \sum_{j=1}^l \lambda_j, \quad (20)$$

where P_k denotes the percentage of each eigenimage contributing to the reconstruction, l is the rank of the matrix, and λ_k represents the eigenvalues in descending order.

In this study, the application of eigenimage extraction using the SVD inversion is verified over a real field Bouguer anomaly from the Jabera-Damoh region, Vindhyan Basin (India). The Jabera-Damoh region has received importance

Inversion Theory in Geoscience, Fig. 3 (a) the Bouguer anomaly map along with the profile under investigation (i.e., AA', as marked by blue line); (b) the reconstructed eigenimages inferred from SVD

inversion on the Bouguer gravity data from the studied region. (Modified after Ganguli and Dimri 2013)

in recent decades due to its potential for hydrocarbon prospects; the national oil and gas company has discovered gas near a borehole at a depth of around 3 km depth. (Ganguli and Dimri 2013). A Bouguer anomaly profile, namely AA' (marked by the blue line in Fig. 3a) from this region was considered for the analysis since it passes through one of the major anomalous parts of this region. The key objective was to identify some important singular geological processes relevant for hydrocarbon prospects in the region through eigenimage analysis. It was identified that about 85% of the total anomalous energy of this gravity signal was dominantly captured by the first eigenimage and the remaining by the second eigenimage. The regional geological structure was efficiently captured by the first eigenimage, while the second eigenimage depicts the local geological characteristics together with noise from different sources (Fig. 3b). Note that the reconstructed eigenimages for the real field gravity data are akin to those derived for a buried faulted structure. In such a case, the sedimentary basin faulted on both margins can be characterized by relatively low (negative) singular values at the center

of the second eigenimage, separating the footwall and hanging wall corresponding to higher and positive singular values (Fig. 3b). The low singular values can be attributed to accumulated sediments of a low density from the studied sedimentary basin. The structure depicted in the second eigenimage may be related to the shallow features and not due to deeper geological bodies since the contribution of anomalous signal in the second eigenimage is always less as compared to the first eigenimage. This observation is further supported by other geophysical and geological studies from this basin, suggesting the study area to be dominated by faulted basin in the crystalline basement. For detailed analysis and interpretation, we refer the interested readers to the work by Ganguli and Dimri (2013).

Summary and Conclusions

The inverse theory is crucial to geoscience studies for inferring the physical properties of the earth system. Here, we

presented an overview of the inverse theory together with its fundamental concepts and two applications to demonstrate the power of inversion in solving seismic and gravity inverse problems. Most direct inversion methods are not powerful to invert the data that are inadequate to recover properties of the earth and contaminated with noise. This unlocked an opportunity for the application of model-based inversion techniques to derive rock properties of interest, which have gained considerable popularity. Much of the success of the inversion method lies in the data quality and forward modeling approach. It is important to have a nominal set of model parameters that fully characterize the system, together with the proper implementation of a priori information and a forward model that can make predictions on some observable parameters based on relevant physical laws. Most of the forward operators are nonlinear and the performance of the inversion algorithm can be arbitrated by how better we elucidate the geoscientific observations knowing their uncertainty. We can get a simple solution if the inverse problem is linearized by imposing a set of limiting conditions to make the forward operator a linear one. Otherwise, iterative methods such as gradient-based methods and random sampling-based search methods can be adapted to solve the geoscientific inverse problems. Several plausible solutions (equally valid) can be derived, owing to the non-uniqueness of the problem. Global optimization methods have been useful to select the final model that attains the global minimum of the objective (misfit) function amidst several minima. These algorithms, however, do not presume any shape of the objective function and are independent of any type of options for starting models. Often highly nonlinear problems can be solved by considering an initial model very close to the peak of the probability density function (PPD) while using these methods. In reality, of course, estimating PPD is quite challenging in a large multi-dimensional model space. We have presented only two applications of inverse theory in geoscience, particularly in seismic and gravity studies. Nevertheless, the application and advanced proposals for the solution of the inverse problems are incessantly intensifying. Physics-guided machine learning-based algorithms for solving large-scale complex systems of equations are receiving augmented attention. With the advent of fast and economical computing facilities, these applications are encouraged and will continue to grow to solve various geoscientific problems.

Iterative Weighted Least Squares

Sara Taskinen and Klaus Nordhausen
Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Definition

Iterative (re-)weighted least squares (IWLS) is a widely used algorithm for estimating regression coefficients. In the

algorithm, weighted least squares estimates are computed at each iteration step so that weights are updated at each iteration. The algorithm can be applied to various regression problems like generalized linear regression or robust regression. In this entry, we will focus, however, on its use in robust regression.

Introduction

Consider a data set consisting of n independent and identically distributed (iid) observations $(\mathbf{x}_i^\top, y_i)$, $i = 1, \dots, n$, where $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})^\top$ and y_i are the observed values of the predictor variables and the response variable, respectively. The data are assumed to follow the linear regression model

$$y_i = \mathbf{x}_i^\top \boldsymbol{\beta} + \epsilon_i,$$

where the p -vector $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)^\top$ contains unknown regression coefficients, which are to be estimated based on the data. The errors ϵ_i are iid with mean zero and variance σ^2 and independent of $\mathbf{x}_i$.

The well-known least squares (LS) estimator for $\boldsymbol{\beta}$ is the $\hat{\boldsymbol{\beta}}$ that minimizes the sum of squared residuals $\sum_{i=1}^n r_i(\boldsymbol{\beta})^2$, where $r_i(\boldsymbol{\beta}) = y_i - \mathbf{x}_i^\top \boldsymbol{\beta}$, or equivalently, solves $\sum_{i=1}^n r_i(\boldsymbol{\beta}) \mathbf{x}_i = \mathbf{0}$. To put this into a matrix form, let us collect the responses and predictors into a $n \times 1$ vector $\mathbf{y} = (y_1, \dots, y_n)^\top$ and a $n \times p$ matrix $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)^\top$, respectively, then the LS problem is given by

$$\underset{\boldsymbol{\beta}}{\operatorname{argmin}} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_2^2, \quad (1)$$

and the estimate can be simply computed as

$$\hat{\boldsymbol{\beta}}_{LS} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{y},$$

assuming that $(\mathbf{X}^\top \mathbf{X})^{-1}$ exists.

If the assumption of constant variance of the errors ϵ_i is violated, we can use the weighted least squares method to estimate the regression coefficients $\boldsymbol{\beta}$. The weighted least squares (WLS) estimate solves $\sum_{i=1}^n w_i r_i(\boldsymbol{\beta}) \mathbf{x}_i = \mathbf{0}$, where $w_1, \dots, w_n$ are some nonnegative, fixed weights. If we let $\mathbf{W}$ be a $n \times n$ diagonal matrix with weights $w_1, \dots, w_n$ on its diagonal, then the WLS estimate can be computed by applying ordinary least squares method to $\mathbf{W}^{1/2} \mathbf{y}$ and $\mathbf{W}^{1/2} \mathbf{X}$. Thus,

$$\hat{\boldsymbol{\beta}}_{WLS} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{y}. \quad (2)$$

If we assume that the errors ϵ_i are independent with mean zero and variance σ_i^2 , then the WLS estimate with weights

$w_i = 1/\sigma_i^2$ is optimal. If we further assume that the error distribution is Gaussian, then the WLS estimate is the maximum likelihood estimate. Notice that in practice the weights are often not known and need to be estimated. Some examples of weight selection are given, for example, in Montgomery et al. (2012). Notice also that linear regression with non-constant error variance is only one application area of WLS.

Iterative Weighted Least Squares

When the weight matrix $\mathbf{W}$ in (2) is not fixed, but may, for example, depend on the regression coefficients via residuals, we can apply the iterated weighted least squares (IWLS) algorithm for estimating the parameters. In such a case, the regression coefficients and weights are updated alternately as follows:

1. Compute an initial regression estimate $\hat{\boldsymbol{\beta}}_0$.
2. For $k = 0, 1, \dots$, compute the residuals $r_{i,k}(\hat{\boldsymbol{\beta}}_k) = y_i - \mathbf{x}_i^\top \hat{\boldsymbol{\beta}}_k$ and weight matrix $\mathbf{W}_k = \operatorname{diag}(w_{1,k}, \dots, w_{n,k})$, where $w_{i,k} = w(r_{i,k}(\hat{\boldsymbol{\beta}}_k))$ with some weight function w . Then update $\hat{\boldsymbol{\beta}}_{k+1}$ using WLS as in (2) with weight matrix $\mathbf{W}_k$, that is,

$$\hat{\boldsymbol{\beta}}_{k+1} = (\mathbf{X}^\top \mathbf{W}_k \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}_k \mathbf{y}.$$

3. Stop when $\max_i |r_{i,k} - r_{i,k+1}| < \epsilon$, where ϵ may be fixed or related to the residual scale.

It is shown in Maronna et al. (2018) that the algorithm converges if the weight function $w(x)$ is non-increasing for $x > 0$, otherwise starting values should be selected with care.

IWLS and Robust Regression

Let us next illustrate how IWLS is used in the context of robust regression, which is widely used in geosciences as atypical observations should not have an impact on the parameter estimation and often should be detected. For a recent comparison of nonrobust regression with robust regression applied to geochemical data, see, for example, van den Boogaart et al. (2021). For a given estimate $\hat{\sigma}$ of the scale parameter σ , a robust M estimate of regression coefficient $\boldsymbol{\beta}$ can be obtained by minimizing

$$\sum_i \rho\left(\frac{r_i(\boldsymbol{\beta})}{\hat{\sigma}}\right), \quad (3)$$

where ρ is a robust, symmetric ($\rho(-r) = \rho(r)$) loss function with a minimum at zero (Huber 1981), or equivalently, by solving

$$\sum_i \psi\left(\frac{r_i(\boldsymbol{\beta})}{\hat{\sigma}}\right) \mathbf{x}_i = \mathbf{0}, \quad (4)$$

where $\psi = \rho'$. Here the scale estimate $\hat{\sigma}$ is needed in order to guarantee the scale equivariance of $\hat{\boldsymbol{\beta}}$. If the estimate is not known, it can be estimated simultaneously with $\hat{\boldsymbol{\beta}}$. For possible robust scale estimators, see, for example, Maronna et al. (2018).

The IWLS algorithm can be used for estimating robust M estimates as follows. Write $w(x) = \psi(x)/x$ and further $w_i = w(r_i(\boldsymbol{\beta})/\hat{\sigma})$. Then the M estimation equation in (4) reduces to

$$\sum_i w_i r_i(\boldsymbol{\beta}) \mathbf{x}_i = \mathbf{0},$$

and the robust M estimate of regression can be computed using the IWLS algorithm. For the comparison of robust M estimates computed using different algorithms, see Holland and Welsch (1977). For monotone $\psi(x)$, the IWLS algorithm converges to a unique solution given any starting value. Starting values, however, affect the number of iterations and should therefore be chosen carefully. Maronna et al. (2018) advice to use the least absolute value (LAV) estimate as $\boldsymbol{\beta}_0$. If the robust scale is estimated simultaneously with the regression coefficients, it is updated at each iteration step. The median absolute deviation (MAD) estimate can then be used as a starting value for the scale. For a discussion on

convergence in the case of simultaneous estimation of scale and regression coefficients, see Holland and Welsch (1977).

Some widely used robust loss functions include the Huber loss function

$$\rho_H = \begin{cases} \frac{1}{2}x^2, & |x| \leq c \\ c\left(|x| - \frac{c}{2}\right), & |x| > c \end{cases}$$

yielding

$$\psi_H(x) = \begin{cases} x, & |x| \leq c \\ \text{sign}(x), c & |x| > c, \end{cases}$$

and the Tukey biweight function

$$\rho_T = \begin{cases} 1 - \left[1 - \left(\frac{x}{c}\right)^2\right]^3, & |x| \leq c \\ 1, & |x| > c, \end{cases}$$

yielding

$$\psi_T(x) = x \left[1 - \left(\frac{x}{c}\right)^2\right]^2 I(|x| \leq c).$$

The tuning constant c provides a trade-off between robustness and efficiency at the normal model. Popular choices are $c_H = 1.345$ and $c_T = 4.685$ which yield an efficiency of 95% for the corresponding estimates. The two loss functions and their derivatives are shown in Figure 1.

Notice that as the Tukey biweight function is not monotone, the IWLS algorithm may converge to multiple solutions. Good starting values are thus needed in order to ensure convergence to a good solution. The asymptotic normality

Iterative Weighted Least Squares, Fig. 1 Huber's and Tukey's biweight ρ and ψ functions with c chosen such that the efficiency at the normal model is 95%.

of robust M regression estimates is discussed, for example, in Huber (1981).

Other Usages of IWLS

Generalized linear models (GLM, McCullagh and Nelder 1989), a generalization of the linear model described above, allows the response variable to come from the family of exponential distributions to which also the normal distribution belongs to. The regression coefficients in GLM are usually estimated via the maximum likelihood method which coincides with the LS method for normal responses. However, for other members from the exponential family, there are no closed form expressions for the regression estimates. The standard way of obtaining the regression estimates is the Fisher scoring algorithm which can be expressed as an IWLS problem (McCullagh and Nelder 1989). The Fisher scoring algorithm creates working responses at each iteration step. Therefore, when using IWLS for estimating coefficients of GLMs, not only are the weights in $\mathbf{W}$ updated at each iteration but also the (working) responses $\mathbf{y}$. How $\mathbf{W}_k$ and $\mathbf{y}_k$ are updated depends on the distribution of the response. For details, see, for example, McCullagh and Nelder (1989). The use of GLMs in soil science is, for example, discussed in Lane (2002).

The idea in robust M estimation described above is to down-weight large residuals, whereas in the LS method, where the L_2 norm is used in the minimization problem (1), these get a large weight. Another way of approaching the estimation is to consider another norm, such as a general L_p norm, which then leads to

$$\arg \min_{\boldsymbol{\beta}} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_p^p,$$

which, for example, for $p = 1$ corresponds to the least absolute value (LAV) regression. It turns out that to solve the L_p norm minimization problem, also IWLS can be used with weights $\mathbf{W}_k = \text{diag}(r_1(\boldsymbol{\beta}_k)^{2-p}, \dots, r_n(\boldsymbol{\beta}_k)^{2-p})$. Uniqueness of the solution and behavior of the algorithm depend on the choice of p . Also residuals, which are too close to zero often, need to be replaced by a threshold value. For more details, see, for example, Gentle (2007) and Burrus (2012). The motivation for using L_p norm in regression is that it may produce sparse solutions for $\boldsymbol{\beta}$ and thus can be used in

image compression such as in hyperspectral imagery (see, e.g., Zhao et al. 2020, for details).

Summary and Conclusion

The iterative weighted least squares algorithm is a simple and powerful algorithm, which iteratively solves a least squares estimation problem. The algorithm is extensively employed in many areas of statistics such as robust regression, heteroscedastic regression, generalized linear models, and L_p norm approximations.

Journel, André

R. Mohan Srivastava
TriStar Gold Inc, Toronto, ON, Canada

Biography

Fig. 1 André Journel (Courtesy Mohan Srivastava)

André Journel is a geostatistician, one of the first group of students to whom Georges Matheron taught his theory of regionalized variables. Educated as a mining engineer at the École Nationale Supérieure de Géologie in Nancy in the late 1960s, he joined the geostatistics research group at Fontainebleau in 1969 and worked there for a decade as a researcher, teacher, and consultant to mining companies around the world. His book *Mining Geostatistics*, co-authored with Charles Huijbregts in 1978, was the first comprehensive and rigorous reference book on the subject, the “bible” for geostatistics for many who explored the mysteries of the new science of spatial interpolation grounded in statistical theory.

In 1978, he became a professor at Stanford University, where he established one of the world’s preeminent geostatistics research programs. In the early 1980s, he moved the application of geostatistics into environmental sciences and championed the theory and practice of risk-qualified mapping. He worked with the US Environmental Protection Agency to create Geo-EAS, the first widely used public-domain software toolkit for geostatistical data analysis and interpolation. In the late 1980s, he and his students at Stanford pioneered many new methods for stochastic simulation, conditioned by hard and soft data. These new algorithms were quickly adopted by the international petroleum industry as the accepted approach for modeling rock and fluid properties in oil and gas reservoirs where correctly representing spatial heterogeneity in computer models of the subsurface is critical for accurate flow modeling and where risk analysis calls for a family of alternate scenarios, all honoring the same input data and user parameter choices.

The principal vehicle for André Journel’s prolific research through the last half of his active academic career was the Stanford Center for Reservoir Forecasting (SCRF), a consortium of industry, government research organizations, and software companies that he founded in 1986 and directed for more than 20 years.

By the time he retired from Stanford in 2010, he had served as the advisor and mentor to more than 50 graduate students and had been the catalyst for two more major public-domain software packages: GSLIB in the 1990s and SGeMS in the early 2000s. He guided the “Applied Geostatistics Series” published by Oxford University Press from its inception in the late 1980s through the early 2000s.

He has been the recipient of many awards and honors, including the Krumbein Medal from the International Association for Mathematical Geosciences (1989), the Earth Sciences Teaching Award at Stanford (1995), the Lucas Gold Medal from the Society of Petroleum Engineers (1998), and the Erasmus Award from the European Association of Geoscientists and Engineers (2012). In 1998, he was elected to the US National Academy of Engineering.

K-Means Clustering

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Clustering is a process of grouping n observations into k groups, where $k \leq n$, and these groups are commonly referred to as clusters. *k-means clustering* is a method which ensures that the observations in a cluster are the closest to the representative observation of the cluster. The representative observation is given by the centroid, i.e., the mean, of the observations belonging to the cluster. This is akin to Voronoi tessellation of observation in a d -dimensional space, if the observations are represented using d -dimensional feature vector. An optimal k -means clustering is one where it achieves minimum intra-cluster, i.e., within-cluster, variance that also implies maximum inter-cluster, i.e., between-cluster, variance. Given a set of observations $(x_1, x_2, \dots, x_n)$ that are distributed/partitioned into k clusters, $\mathbf{C} = \{C_1, C_2, \dots, C_k\}$, such that $k \leq n$, then the objective function for optimization is given by:

$$\arg \min_{\mathbf{C}} \sum_{i=1}^k \sum_{\mathbf{x} \in C_i} \|\mathbf{x} - \boldsymbol{\mu}_i\|^2 = \arg \min_{\mathbf{C}} \sum_{i=1}^k |C_i| \sigma^2(C_i),$$

where $\boldsymbol{\mu}_i$ is the mean of the observations in the cluster C_i and $\sigma^2(C_i)$ is its intra-cluster variance. Intra-cluster variance is defined as the variance of the position coordinates of the observations in a cluster, i.e., given by the sum of squared Euclidean distances of all observations in the cluster with all the others within the same cluster. Similarly, inter-cluster variance refers to the sum of the distance of the observations belonging to two different clusters.

Euclidean distance or the L^2 norm of the distance vector is conventionally used in k -means clustering. The use of Euclidean distances manifest as nearly spherical clusters. Thus, k -means clustering works the best for observations which are inclined to have spherical clusters. Other distance measures, such as Mahalanobis distance and cosine similarity, can also be used (Morissette and Chartier 2013). If the distance measure used is the Mahalanobis distance, then the covariance between the vectors of observations is considered. Similarly, if the distance measure is the cosine similarity, then correlation is used as the distance measure. Thus, the characterization of the distance measure influences the clustering outcomes.

Overview

The term *k-means* was first coined in the context of qualitative and quantitative analysis of large-scale multivariate data (MacQueen et al. 1967). The Lloyd-Forgy algorithm (Forgy 1965; Lloyd 1982) is the classical implementation that is widely used today and is also referred to as the naïve k -means. The algorithm, in both Lloyd-Forgy and MacQueen variants, comprises six key steps: (i) choose k , (ii) choose distance metric, (iii) choose method to pick centroids of k clusters, (iv) initialize centroids, (v) update assignment of membership of observation to closest centroid, and update centroids. Step (v) is implemented iteratively until convergence, which is determined by no change from previous iteration. Apart from convergence, the termination condition could also be imposed by forcing the number of iterations.

Now, the difference in both variants is in the manner of implementation of step (v). In the MacQueen algorithm, only observation is updated at a time, causing centroids to be updated, whereas in Lloyd-Forgy algorithm, the membership of all observations to the clusters is updated, and then the centroids are updated. Thus, MacQueen algorithm is an *online/incremental algorithm*, and Lloyd-Forgy algorithm is

an *offline/batch algorithm*. The former is efficient owing to frequent updates of centroids, whereas the latter is better suited for analyzing large datasets. The Lloyd and Forgy algorithms themselves differ in a minor point of considering the data distribution to be discrete and continuous, respectively. The Lloyd-Forgy algorithm is considered to be analogous to a spatial partition algorithm, specifically Voronoi tessellation.

Hartigan-Wong implementation, unlike the Macqueen and Lloyd-Forgy variants, focuses on achieving the objective function for optimization using the local minima as opposed to the global minimum (Hartigan and Wong 1979). It follows the aforementioned steps (i)–(v), followed by an additional step (vi) compute the within-cluster sum of squares of errors (SSE) to locally optimize. It means that when a centroid of a cluster, say C_i , is updated in the last iteration, the within-cluster SSE is compared with the within-cluster SSE if an observation currently in C_i were to be in another cluster C_j , such that ($i \neq j$). It does not guarantee a global optimum and hence, is a heuristic. Hartigan-Wong algorithm, like the Macqueen one, is sensitive to the order of change of cluster membership of the observations.

The pros of the basic iterative implementation of the k-means clustering algorithm include its relatively simple implementation and guaranteed convergence. But, its cons include the requirement of the number of clusters k as an input and the initialization of centroids prior to the iterative implementation. While the latter is conventionally done using random values, there are several methods which improve the initialization, e.g., using progressive methods, structured partitioning, a priori information, hierarchical clustering (Ward's method), etc. The k-means algorithm also suffers from the curse of dimensionality, as the ratio of the standard deviation to the mean of distance between observations decreases with increase in the number of dimensions. As the ratio decreases, the k-means clustering algorithm becomes increasingly ineffective in distinguishing between the observations. The curse of dimensionality can be alleviated using spectral clustering by projecting the observations to a lower dimensional subspace of k -dimensions, using principal component analysis, and then performing k-means in the k -dimensional space.

Owing to the popularity of the algorithm, several improvements have been implemented on the k-means algorithm. The effectiveness of the algorithm can be measured using internal and external criteria. Internal criterion is a metric that measures if the global optimum has been reached, and the external criterion measures the similarity of the current partition with a known partition, e.g., ground truth. Dunn index and Jaccard similarity are examples of internal and external criteria, respectively. k-means algorithm is an unsupervised learning method, as it does not require training data for pattern matching.

Applications

The pros of the algorithm satisfy its two significant goals, namely, exploratory data analysis and reduction of its complexity (Morissette and Chartier 2013). Geoscientific and related datasets have the characteristics of unknowns in the data and of being large-scale and complex. Thus, k-means clustering is widely used in different geoscientific domains and for different types of data analysis. The examples in seismology, flood extent change detection from synthetic aperture radar (SAR) images, and land cover change detection (LCCD) from satellite images are covered as samples of the specific problems in different domains that use k-means clustering. The examples in clustering for machine learning and visualization tool show how k-means clustering is a tool or a method integrated with a data analysis toolkit or application. Overall, these examples demonstrate how k-means clustering is one of the standard data analysis methods used in geoscience.

The k-means algorithm has been used in seismology for probabilistic seismic hazard analysis, where k-means is used to obtain a partition of earthquake hypocenters or alternatively a partition of fault ruptures (Weatherill and Burton 2009). The initialization of cluster centroids is done using ensemble analyses for identifying best choices. The k-means partitions of seismicity are then used as source models, whose representation in the regional seismotectonics is studied. The assessment shows that the k-means algorithm has given clusters that provide the most appropriate spatial variation in hypocentral distribution and fault type in the region. Similarly, k-means can be applied to features representing earthquake waveforms to study temporal patterns in low-magnitude earthquakes in geothermal fields. This indicates the usefulness of the k-means algorithm in solid Earth geosciences.

Change detection is done from multitemporal data, e.g., SAR and satellite images. Flood extent mapping has been done by change detection in SAR by using a combination of techniques using a two-step process (Zheng et al. 2013). Firstly, the difference image of SAR images of a region from two consecutive time-stamps is computed. After applying median and mean filters on the difference image, and the outcomes are combined, k-means algorithm is applied as a second step to cluster changed and unchanged regions. k-means algorithm has been found to be effective in capturing spatial variations in the difference image. Similar method can be applied for LCCD in remote sensed images, i.e., Landsat images (Lv et al. 2019). In addition to the aforementioned two steps, there is an additional step of adaptive majority voting (AMV) in local neighborhoods to identify the class type for land cover to analyze urban expansion, urban build-up changing, deforestation, etc. Majority voting is an ensemble analysis method. Overall, such integrated methods that include

efficient methods, such as the k-means algorithm, provide flexibility of applications and generality of change.

In addition to unsupervised learning applications, k-means algorithm has been used to reduce complexity in geoscientific data that is further visualized using appropriate metaphors (Li et al. 2015). For instance, geoscientific observation stations can be clustered for providing overview of the data, and these clusters are represented using simplified data visualization layouts, e.g., radial layout.

Future Scope

Geoscience and related datasets are now classified as big data, owing to the volume, velocity, variety, value, and veracity, i.e., the five Vs. Such complex data requires high-performance computing for its analysis. Hence, graphics processing unit (GPU)-based large-scale computations are implemented which entails hardware accelerated implementation of the algorithms, including k-means algorithm (Yu et al. 2019). The use of GPUs enable automatic hyperparameter tuning which allows the scalability of k-means algorithms to large datasets and also improving the potential of the algorithm for various applications. Parallel implementation of k-means has been used with real-world geographical datasets. Given the increasing complexity of the geoscientific and geographical data and metadata, there is potential for both hardware and software enhancements to be fulfilled, for the k-means algorithm.

Overall, k-means algorithm is an effective and efficient clustering algorithm that has been successfully used on geoscientific datasets.

K-Medoids

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International Institute of Information Technology Bangalore, Electronic City, Bangalore, Karnataka, India

Definition

A *medoid* is defined as a representative item in a dataset or its subset (or cluster), which is *centrally located* and has the least sum of dissimilarities with other items in the group (Kaufman and Rousseeuw 1987). Medoids are identified in a dataset to implement partitioning around medoids (PAM), which is a clustering method. Since PAM is used to generate K clusters, where K is a user-defined positive integer, such that $K > 1$, this method is also referred to as K-medoids clustering method (Kaufman and Rousseeuw 1987). A medoid is not equivalent to other statistical descriptors of median, centroid, or mean, but is the closest to median by virtue of an item in the dataset serving as a representative, as opposed to a computed entity. A median is identified by sorting items with respect to a single variable and picking the “middle” value of the variable, whereas the medoid is the item itself. Hence, medoids can be considered to be more generalized since it represents multivariate or multidimensional space, with flexibility in identifying them, based on the usage of appropriate dissimilarity or distance measures. Given that the rest of the article impresses upon geoscientific application, “item” will be referred to as “point” hereafter.

Overview

K-medoids clustering is often compared with the K-means one (*see the article on “K-Means Clustering”*), owing to the similarity in the algorithms. A key difference in both these partitioning algorithms is that the cluster representative or center is an actual point in the case of K-medoids method, i.e., the medoid itself (Kaufman and Rousseeuw 1987),

K-Medoids, Fig. 1 A graphical representation of the key difference in the cluster representative or the cluster center identified in (left) K-medoids and (right) K-means clustering algorithms. The magenta box indicates the cluster center, for a cluster of sites (blue circles)

indicated by its boundary (red dotted curve). (Image courtesy: Author's own, but adapted from a diagram in the article by Jin and Han (2011) https://doi.org/10.1007/978-0-387-30164-8_426)

whereas a centroid is computed from the points present in the K-means cluster. Traditionally, by design, another important difference between the two methods existed that revolved around the constraint of use of Euclidean distance in K-means, which was generalized to any similarity measure in K-medoids. Thus, the first implementation of PAM (Kaufman and Rousseeuw 1987) focused on introducing the use of dissimilarity measures, e.g., one minus Pearson correlation, to be a governing factor in the partitioning algorithm. Over time, Euclidean distance, one minus absolute correlation, and one minus cosine similarity have also become widely used dissimilarity measures (Van der Laan et al. 2003). K-medoids clustering problem is known to be NP-hard and hence has approximate solutions (Fig. 1).

The implementation of the original PAM has two steps, INITIAL and SWAP. INITIAL starts with D , a $n \times n$, dissimilarity matrix for n points, and M is a set of initial seed points of size K , used as medoids, for K clusters. Each point is associated with a seed point by virtue of its lowest dissimilarity with the seed point, i.e., its corresponding medoid. Then, SWAP is done iteratively which minimizes the optimizes M by minimizing the loss function, i.e., the sum of dissimilarities of each point and its corresponding medoid. In the SWAP step, each medoid is considered for a *swap of roles* with a non-medoid point, and the swap is implemented only when the recomputed loss function is minimized. This greedy algorithm terminates when SWAP does not find any more changes for implementation and is thus more efficient than an exhaustive search method.

The original PAM algorithm recommends determining a data-driven K value by maximizing the average silhouette. The silhouette is computed based on the outcome of the implementation of PAM with a random K value (Kaufman and Rousseeuw 1990). PAM has been alternatively solved using the loss function that is the sum of maximum dissimilarity between a point and its corresponding medoid (Kaufman and Rousseeuw 1990). This methodology has been referred to as the K-center model.

PAM has been extended to cluster large datasets using a sampling strategy. This variant of PAM is called CLARA (clustering large applications) (Kaufman and Rousseeuw 1990). CLARA involves two steps, where the first step involves finding a sample in the large dataset and implementing PAM on this sample or subset, and the second step entails adding the remaining points (outside of the sample) to the current set of medoids. After the clustering of the entire dataset is completed, the medoids can be recomputed, as required.

CLARANS (clustering large applications based on randomized search) has been a further improvement over PAM and CLARA, using an abstraction of a hypergraph (Ng and Han 2002). A graph is constructed in such a way that each node is a set of K objects, such that they can be potentially medoids, and two nodes are neighbors only when the cardinality of their set intersection is $K - 1$. Thus, a node is an abstraction of an instance of the partition or clustering itself. PAM is now implemented on this graph as a search for the node with the minimum cost by going from an initial random node to a neighbor with the deepest descent in costs. CLARANS has been proven to run efficiently on large databases too.

The attractive characteristic of PAM is in its flexibility of distance or similarity measures that can be used as per the semantics needed in the clustering. Medoids are specific cluster representatives, unlike the cluster centers used in similar partitioning methods are less sensitive to outliers (Van der Laan et al. 2003). In hierarchical clustering methods, the representative points used as medoids can be effectively used. This is owing to the completeness of data in all dimensions for the medoids, just as any other point in the data, whereas the computed cluster centers usually have the attributes only for the subset of dimensions used for the clustering process. While PAM does not find good clusters when the cluster sizes are unbalanced or skewed, this can be resolved by using the silhouette function as the cost function in the PAM algorithm (Van der Laan et al. 2003).

The implementation of PAM is still inefficient and has time complexity of $O(K^3 \cdot n^2)$ (Xu and Tian 2015), which is improved by implementing the distance matrix only once and iteratively finding new medoids, by running several methods to identify the initial medoids (Park and Jun 2009). This algorithm is referred to as a “K-means like” algorithm, which improves the efficiency of PAM. This faster algorithm has a time complexity of $O(K(n - K)^2)$, which is high compared to the time complexity of CLARA, which is $O(K^3 + nK)$, and to that of CLARANS, which is $O(n)$, which also has to include its characterization of a randomized algorithm.

Applications

This method is applicable to all datasets involving scattered points, which includes both geospatial locations and large collections or databases of definite objects, e.g., images, vector data (cartographic maps), and videos.

One such example of clustering spatial points is that of ARGO buoys in the ocean done using an improved K-medoids method for anomaly detection in the ocean data (Jiang et al. 2019). This entails including a density criterion in identifying the initial seed points for running the K-medoids algorithm. For each cluster, the points that do not belong to the dense regions of the cluster are identified as outliers. In such an application, it has been found that the density-based approach in the K-medoids algorithm has improved the results by a higher accuracy score and a lower false detection rate. Similar applications have been found in the spatial clustering of traffic accidents.

As an example of clustering of objects, different from geospatial locations, K-medoids have been used for clustering and classification of remotely sensed images of snowflakes acquired using a multi-angle snowflake camera (MASC) (Leinonen and Berne 2020). In this specific example, a generative adversarial network (GAN) is used for feature extraction from the images, and then, the feature vectors are clustered and classified using K-medoids and hierarchical clustering.

Future Scope

As observed, one of the key criticisms against the K-medoids algorithm is its high run-time complexity, which has been the scope of improvement in the current and future work on this method. There are several improvements that have already been proposed. One such example is in the parallel implementation of the K-medoids algorithm, PA-MAE (parallel k-medoids clustering with high accuracy and efficiency) (Song et al. 2017). PAMAE implements a two-phase method, namely, parallel seeding and parallel refinement, for improving accuracy and efficiency. These phases are implemented in

the form of MapReduce, which enables parallelism. Parallel seeding involves identifying a sample of points in the large dataset and conducting a global search over this subset of the points. The parallel refinement is in MapReduce that involves performing a local search in the entire dataset. The difference between local and global searches is in finding a new medoid within a considered group vs outside of the group, respectively. This method is designed to be implemented on Spark and Hadoop, which are both horizontally scalable big data frameworks.

Faster implementation of PAM has been achieved by relaxing the number and choice of swaps in the SWAP step, e.g., FastPAM (Schubert and Rousseeuw 2019). This strategy is flexible to be incorporated with variants of PAM implementations, such as CLARA and CLARANS algorithms. FastPAM works by removing redundancy in computations for finding the best swap in PAM and swapping for multiple medoids simultaneously, owing to the independence of clusters.

Another line of work on the K-medoid method is in incorporating it as a step in data science workflows, such as that for the classification of snowflake images (Leinonen and Berne 2020). Such integration is usually challenging when the method has to be coupled with another data mining method. In that regard, the flexibility built into the K-medoids clustering both in terms of choice of dissimilarity measure and initialization method for the seed points is useful in coupling it with other methods, such as feature extraction, feature ranking, etc.

In summary, K-medoids clustering is a partitioning algorithm that provides robust cluster representatives which have proven to be useful across several geoscientific applications. Thus, this method has been successfully used for more than three decades.

K-nearest Neighbors

Jaya Sreevalsan-Nair
Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

The k-nearest neighbors (kNNs) generally refer to the kNN algorithm that was initially proposed as a nonparametric solution to the *discrimination problem* (Fix and Hodges 1951). The discrimination problem refers to that of determining if a random variable Z with an observed value z is distributed over a p -dimensional space according to parametric distributions F or G . There are three variants of the problem, where both F and G are (i) completely known; (ii) known, but parameters are unknown; and (iii) completely unknown. The seminal solution proposed for the variant (iii), now known as the kNN algorithm, uses a nonparametric approach. It is given that there are m samples, $\{X_i \mid 0 \leq i < m\}$ and n samples, $\{Y_i \mid 0 \leq i < n\}$, of F and G , respectively. The solution says that if the k -nearest neighbors of z include M X s and $N = (k - M)$ Y s, where $(k, M, N \in \mathbb{Z}^+)$, $(k < m)$, $(k < n)$, then using likelihood ratio discrimination, Z , can be assigned to F iff $\left(\frac{M}{m} > c \frac{N}{n}\right)$, where c is an appropriate positive constant. This is the nonparametric counterpart of the parametric condition used to solve variants (i) and (ii), i.e., $\left(\frac{f(z)}{g(z)} > c\right)$, using density functions f and g , of F and G , respectively. This proposed approach is now known as the *majority voting*.

Over time, the kNN algorithm has been reframed as a *classification method*, where, in the absence of the parametric class distributions of a set of labeled objects S , a new object

X is assigned a class label, i.e., the label of a majority of the objects in k objects from S , closest to X . Thus, a majority voting approach is implemented on a predetermined set of labeled local neighbors of X , $\mathcal{N}(X)$, where its set cardinality is k , for determining the class label of X . The closeness between objects is defined using pairwise *distance functions*, e.g., Euclidean distance. Given two objects X and Y , defined using attribute/feature vector $a \in \mathbb{R}^p$, the Euclidean distance is given by

$$d(X, Y) = \|a(X) - a(Y)\|_2 = \sqrt{\sum_{i=1}^p (a_i(X) - a_i(Y))^2}.$$

Given $\mathcal{N}(X) \subset S$, such that $\mathcal{N}(X) = \{Y_1, \dots, Y_k\}$ and the class labels set C , the majority voting gives the class label of X as

$$\begin{aligned} c(X) &= \arg \max_{c \in C} \sum_{i=1}^k \delta(c, c(Y_i)), \text{ where } \delta(c, c(Y_i)) \\ &= \begin{cases} 1, & \text{if } c = c(Y_i), \\ 0, & \text{otherwise.} \end{cases} \end{aligned}$$

Overview

The basic kNN algorithm using majority voting has been improved using several strategies (Jiang et al. 2007). The use of Euclidean distance leads to inaccuracies in the presence of irrelevant features, which is referred to as the *curse of dimensionality*. Hence, strategies such as the use of optimal feature subsets based on feature ranking or filtering, attribute weighting using mutual information, frequency-based distance measure, etc. have been successfully used to overcome the curse of dimensionality. Adaptive or dynamic kNN involves identification of an optimal k value for each object prior to running the kNN algorithm or other related methods.

The kNN algorithm is now extended beyond classification owing to the versatility of applications of the k-nearest neighbors (kNNs) themselves. The set of kNNs of an object X , $\mathcal{N}(X)$, can now be defined as its local neighborhood that can have different variants based on the choice of the distance function, which includes other distance measures, e.g., Hamming, Chebyshev distances, etc. The use of kNNs now include feature extraction, segmentation, regression, and other data mining processes. Generalizing the use of kNNs across all these applications entails applying appropriate (function) *map* on a specific property, q , of each of the local neighbors of X and subsequent *reduce* operation, i.e., accumulation functions, to determine the value of q at X . q is now generalized as class label, value of a feature in its hand-crafted feature vector, global or local descriptor, etc. In the basic kNN algorithm, the map is an identity function on class label, as q , and the majority function is used for accumulation. As an

example of generalized application, in LiDAR (light detection and ranging) point cloud processing, the position coordinates of 3D points serve as q , the covariance matrix between a 3D point and its neighbor is the map, and the matrix sum is a reduce operation, which gives the design matrix (Filin and Pfeifer 2005). This matrix serves as the local geometric descriptor of the 3D point, required for feature extraction for point cloud classification. The local neighborhood used for the LiDAR points can be of kNNs or of spherical, cuboidal, or cylindrical shape.

Applications

There are several geoscientific applications for which both kNN algorithm and kNNs have been successfully used. There has been a long history of classification problems pertaining to digital maps and satellite remote sensing image data for both pixel-based and image classification, for which kNN algorithm and its variants are useful. These examples here demonstrate that the kNN algorithm works effectively on different types of remote sensed images for domain-specific classification problems.

- As an example of pixel-based classification, delineation of forest and non-forest land use classes has been done using kNN algorithm to classify plot pixels on digital map data, routinely used in Forest Inventory and Analysis (FIA) monitoring (Tomppo and Katila 1991). Satellite imagery and field data from FIA have been used to improve the weighting distances used in kNN method. The field data also serves as ground truth. The classification is used for constructing maps for basal area, volume, and cover type of the forests. kNN has been widely used for forest map delineation as it is effective for mapping continuous variables, e.g., basal area, volume, and cover type. Another reason for quick adoption of the kNN algorithm by the FIA community has been its easy integration with existing systems and methods.
- In another example of pixel-based classification involving hyperspectral images (HSI), kNN algorithm with guided filter has been effective in extraction of the information of the spatial context as well as denoising classification outcomes using edge-preserving filtering (Guo et al. 2018). HSI classification involves using spectral features of pixels to classify them into different classes, e.g., different types of soil types, plant species, etc. The joint representation of kNN and guided filter has been found to work the best with the full feature space, without performing any dimensionality reduction.
- As an example of image classification, for that of infrared satellite images to six different cloud types, kNN classifier has been found to be more accurate than the neural network using self-organizing feature map (SOFM) classifier, when applied to different texture features (Christodoulou et al. 2003). kNN classifier with weighted averaging has

also performed better than the traditional majority voting for cloud satellite image classification.

Apart from classification, kNN regression has been widely used in geoscientific applications for prediction and estimation. As an example of regression, estimating ground vibrations in rock fragmentation is considered. Blasting is routinely used for rock fragmentation, and estimating the blast-induced ground vibration is an important problem to study the effect of blasting in the surrounding environment. A combination of kNNs and particle swarm optimization (PSO) has been effectively used for estimating the peak particle velocity (ppv) that is a measure of the ground vibration (Bui et al. 2019). Here, the kNNs are used as the specific observations that influence the output predictions in a regression model. The optimization of particle positions using the PSO algorithm enables improving the precision of the kNN regression.

kNNs are effective for value replacement in several geoscientific applications. An example is in the use of nearest neighbors in improving the analysis of the geochemical composition of soil. For $k = 1$, kNN approach is used to replace values screened of several elements (e.g., Al, C, Ca, Na, P, etc.) at sample sites (Grunsky et al. 2018). Usually, there are observations for several elements where the values are less than the lower limit of detection ($<LLD$), which is undesirable. For such cases, the data is adjusted using the values observed in the neighbors. This adjusted data is further used for multivariate statistical analysis of the soil in the study area.

Overall, the kNN algorithm and the data models using kNNs have helped in creating powerful data processing and mining tools.

Case Study: LiDAR Point Cloud Processing – For LiDAR point clouds, the shape of the local neighborhood of a point is a significant differentiator in classifying the point. The local neighborhood itself is determined by using specific constraints on search for the neighbors. The search query includes finding points present in a search volume or *support region* of a specific size, e.g., kNNs, or of a specific shape, e.g., spherical, cylindrical, cuboidal, etc. (Filin and Pfeifer 2005). A combination of constraints can be used for support region, e.g., kNNs of a specific k value within a spherical neighborhood of a specific radius. The search query itself is implemented using efficient spatial data structures, such as kd-trees, octrees, etc. While the direct use of the kNN algorithm is rare in LiDAR point cloud classification, kNNs are used for feature extraction (Weinmann et al. 2014).

Prior to feature extraction for classification, a local geometric descriptor is computed at each point using the selected local neighborhood. The descriptor upon eigenvalue decomposition contributes to the eigenvalue-based features for classification. It is now known that a single support region is not sufficient to obtain an optimal descriptor for classification, owing to the inherent uncertainty in the data. Hence, increasingly multiscale methods are used in LiDAR point cloud processing. The size of the support region is considered to

be the *scale*. Thus, for kNNs, the different k values are used as scales. Identifying an *optimal scale* from multiple scales and using the features computed at the optimal scale for classification have been found to improve classification accuracy (Weinmann et al. 2014). Identifying multiple scales is the most straightforward when using kNNs, as opposed to other types of support regions, as the different scales can be identified by using all positive integer values. The use of optimal neighborhood using kNNs, where optimality is identified based on global minimum of eigen-entropy, has been found to improve classification accuracy.

Segmentation and classification of 3D point cloud can be largely seen as variants of the clustering or the grouping problem. Thus, segmentation of LiDAR point clouds to extract localized objects, e.g., buildings, use kNNs to group the specific set of points for geometric reconstruction (Wang and Shan 2009). There are two types of edges that can be reconstructed in the buildings from the LiDAR point clouds, namely, the jump edges and the crease edges. The jump edge is a discontinuity in height values, and the crease edge is where two surfaces intersect. Jump edges are critical in segmenting the point cloud into surface patches that identify objects such as the ground, buildings, etc. kNNs are instrumental in identifying points on the jump edges and in the jump edge extraction. Thus, kNNs play a central role in different point cloud processing methods.

Future Scope

Given the advent of supervised learning and deep learning for classification, the use of kNN algorithm and kNNs in general has become indispensable in data mining and knowledge discovery in geoscientific datasets. Given the ease of implementation, integration, and enhancement of kNN algorithm, it will continue to be used for classification, regression, and several other data mining methods, applied on images, point clouds, grids, and other data types used in geoscience.

Biography

Andrey Nikolayevich Kolmogorov was born in 1903 in Tambov, 50 km from Moscow. His talent for mathematics showed at the age of 5 when he discovered a remarkable property of the integer numbers: $1=1^2$, $1+3=2^2$, $1+3+5=3^2$, $1+3+5+7=4^2$, etc. In 1920, he graduated from high school and went to Moscow State University. As a student, he constructed a Fourier series that diverges almost everywhere (Kolmogorov 1923). He graduated in 1925, obtained his

Doctor of Philosophy Degree in 1929, and became a professor at Moscow State University in 1931. Later, in addition to performing research and teaching, he occupied various administrative positions at this university. This included serving as Dean of the Department of Mechanics and Mathematics. In 1939, he became a full member of the USSR Academy of Sciences. From 1930 onward, he made several trips abroad to visit colleagues. He also participated in several scientific conferences organized outside the Soviet Union. His fruitful life ended in 1987.

Kolmogorov is probably best known for his book “Foundations of the Theory of Probability” that contains the widely accepted axioms which provided mathematical statistics with its sound basis (Kolmogorov 1933). He made numerous other contributions to mathematics and science. For example, Kolmogorov (1941a) contains the original theory on turbulence in fluids for large Reynolds’ numbers that later was seen as the earliest multifractal cascade model. A complete list of his 518 publications can be found in the *Annals of Probability* (1989, Vol. 17, No. 3). They include 119 contributions to the second edition of the *Large Soviet Encyclopedia* (in Russian). After 1964, relatively many of Kolmogorov’s publications were concerned with the teaching of mathematics and statistics in Russian high schools. His name is remembered in many theorems and statistical methods including the Chapman-Kolmogorov and Fisher-Kolmogorov equations and the Kolmogorov-Smirnov test.

Several times, Kolmogorov contributed to mathematical geoscience: Kolmogorov (1941b) discusses a modification of the central limit theorem to explain lognormality of grain-size distributions in sedimentary petrology. He was a mentor of Andrew Vistelius who is considered to be a father of mathematical geology (cf. Henley 2018). In 1975, I visited Vistelius when he was the director of the “Laboratory of Mathematical Geology” in Leningrad. During discussions in his large private apartment, Vistelius enumerated the invaluable help he had received from Kolmogorov who helped him in 1948 to become the youngest Doctor of Science in the USSR. Vistelius had arranged for me to meet with Kolmogorov in Moscow, but this visit could not take place for medical reasons. Two publications of Kolmogorov are related to projects on which Vistelius had been working as well. These are the geometric configuration of crystals in igneous rocks (Kolmogorov 1949a) and the deposition of strata in sedimentary basins (Kolmogorov 1949b).

Biography

Professor Gabor Korvin, Applied Mathematician, Geophysicist, Petrophysicist, Historian. He was born in Hungary (1942), has M. Sc. in Applied Mathematics (1966, Univ. Nat. Sciences, Budapest, Hungary); Ph.D. in Geophysics (1978, Univ. Heavy Industries, Miskolc, Hungary); Graduate

Diploma in Islamic Studies (1998, Univ. New England, Armidale, Australia).

Between 1966 and 1985 he was exploration seismologist and software developer in the Hungarian Geophysical Institute, Budapest; in 1986–1991 Senior Lecturer, University of Adelaide, Australia; 1994–2016 (when he retired) Professor of Geophysics, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran, Saudi Arabia. At KFUPM he was Coordinator of the *Reservoir Characterization Research Group*. As Professor, he taught *Reservoir Characterization, Seismic Stratigraphy, Petrophysics & Well logging, Solid Earth Geophysics, Geoelectric Exploration, Reflection Seismology, Inverse Problems, Geostatistics*.

He has more than 80 papers. His book *Fractal Models in the Earth Sciences* (Amsterdam, Elsevier, 1992a) was internationally acclaimed. His publication on resistivity anisotropy in thinly laminated sand-shale received the *Best Petrophysics Paper in 2012 Award*. His main Research Interest lies in finding stochastic mathematical and physical models to describe sedimentary rocks. He used the most diverse fields of mathematics and physics to solve petrophysical problems, such as: Gaussian random fields (1973, 1977, 1981); effective field theory (1982, 2012); fractals (1992a); and Percolation Theory (1992b). In 2014 he worked out a new rock model to connect different petrophysical properties. For some 20 years he was Earth Sciences Editor of the *Arabian Journal of Science and Engineering* (AJSE, Dhahran, Saudi Arabia). On the occasion of his retirement he wrote a Review Paper for this Journal on his dreams about the stochastic approach to Petrophysics (2016). He also publishes in Theoretical Mathematics (*Number Theory, Combinatorics*) and on Cultural and Religious History.

Krige, Daniel Gerhardus

Richard Minnitt

School of Mining Engineering, University of the Witwatersrand, Johannesburg, South Africa

Fig. 1 Professor Daniel Gerhardus Krige, 26 August 1919–12 March 2013 © International Association for Mathematical Geosciences 2013, Courtesy of Ansie Krige

Biography

Daniel G. Krige has global recognition in the mining industry as the pioneer of modern statistical methods of ore evaluation known as geostatistics. His surname describes geostatistical techniques of “kriging,” applied worldwide in exploration, ore evaluation, environmental, petroleum, hydrology, agriculture, and other disciplines. Born in Bothaville on 26 August 1919, Danie graduated as a mining engineer in 1938 at the University of the Witwatersrand. He worked on various gold mines until 1943 after which he joined the Government Mining Engineer’s Department where he pioneered statistical applications to mineral valuation and ore reserve estimation of gold mines in the 1950s (Krige 1951, 1952). The rapid development of the Free State and Klerksdorp goldfields meant that decisions about mining investments based on limited numbers of boreholes were made without assessing the risk of failure. It was this that stimulated Danie’s research into ore evaluation. Apart from the lognormal frequency distribution model devised by Herbert Sichel in South Africa (Sichel 1947, 1952), approaches to statistical mine evaluation were unknown. The statistical explanation of the notorious problem of conditional bias in routine ore block and reserve valuations, given by Krige (1951), led several gold mines to use elementary regression correction techniques based on what is now known as kriging. Basic geostatistical concepts

of “support,” “spatial structure,” “selective mining units,” and “grade-tonnage curves” were introduced by Krige (1952).

Following the translation of his 1951 publication on the statistical approach to mine evaluation, interest among French mining engineers in the new field of geostatistics grew, leading to the establishment of Le Centre de Géostatistique de l'École des Mines de Paris in Fontainebleau. The term “kriging,” coined by Georges Matheron, describes the mineral evaluation process leading to improved estimates and reduced financial uncertainty about mining investments. Danie implemented the first routine application of the kriging of ore reserves on two large gold mines belonging to Anglovaal in the early 1960s. His research and publication of some 90 technical papers on the practical application of regionalised variables and spatial evaluation of mineral resources and reserves, is as a result, deeply entrenched in the mining industry.

Danie's work in geostatistics continued until he retired from Anglovaal in 1981. Following retirement, he held a position as Professor of Mineral Economics at the University of the Witwatersrand until 1991 and continued to consult to the mining industry until 2010. His contributions were recognized by the University through the award of the D.Sc. (Eng.) degree in 1963, by three honorary degrees (from the universities of Pretoria, UNISA, and Moscow State Mining University), by many awards from the South African Institute of Mining and Metallurgy, the International Association for Mathematical Geosciences, Die Suid Afrikaanse Akademie vir Wetenskap en Kuns, the SME of the American Institute of Mining Engineers, the International APCOM Council in 1999, the University of Antofagasta in Chile, and by the South African President (Order for Meritorious Service, Class 1, Gold). He was a fellow and honorary life member of various technical societies locally and overseas, including the Royal Society of South Africa. In recognition of Danie Krige's distinguished contributions to engineering, he was elected a Foreign Associate of the United States National Academy of Engineering (NAE) Section 11, Earth Resources Engineering, in February 2010. Danie is the first South African to ever receive this award from the NAE.

Kriging

Xavier Freulon and Nicolas Desassis
Mines ParisTech, PSL University, Centre de Géosciences,
Fontainebleau, France

Synonyms

Gaussian process regression; Kolmogorov-Wiener prediction; Spatial best linear unbiased prediction

Definition

Kriging is a geostatistical procedure to estimate the value of a variable of interest from its measurements at some sampling locations. Kriging weights are determined by two conditions: the value to be estimated and its estimator share the same average value; the variance of the estimation error, also called prediction variance, takes the smallest possible value.

Prediction based on kriging is equivalent to spatial best linear unbiased predictor (or BLUP) where, for a given covariance function, the predictor minimizes the mean-squared prediction error over all linear combinations of observation values. The support of the target value can be punctual or volumic (e.g., the grade of a block); in this latter case, the estimated value is the average value over the support and is computed from samples located inside or outside this volume.

Some History

In geosciences, most of the observed variables vary continuously in space showing high irregularity at the local scale and some trends with a larger scale. Viewed mathematically, the value of the property of interest is a function of its position that cannot be expressed by some simple and closed expression. A practicable approach is to regard such a property as a random variable and to treat statistically its variation in space. Matheron (1962) coined such properties as regionalized variables and geostatistics, as the application of probabilistic methods to such variables.

Geostatistics stems largely from mining, and its terminology retains a strong mining flavor: one of the tasks of the mining engineer is to select the blocks to be exploited. To simplify, a block deserves to be exploited only if the cost of its extraction and processing does not exceed the value of its metal content. In practice, the true grade of a block is not known before its exploitation, so that the selection is made on the basis of an estimated grade. Thus improving the estimation of ore concentration in rock and of recoverable mining resources from fragmentary information (i.e., scarce drill holes) is a key operational issue. At the beginning of the 1950s, this estimate was simply the average grade of the data belonging to the block or situated at its border. Krige (1951), studying exploitation data in goldfields of South Africa, observed that for high cutoffs the blocks selected by this way were on average less rich than expected. Mathematically, this expresses a conditional bias. To avoid this bias, Krige gave a weight to the average grade of the data situated in the block and the complementary weight to the average grade of the ore body, these weights being determined by linear regression. Matheron (1962) generalized Krige's regression by assigning a proper weight to each sample, these weights being determined so as to minimize the estimation variance under the condition that the weight sum to 1 (this condition simply expresses that the estimator is a weighted average of the data), and he called this method kriging in honor to Danie G. Krige.

The principle of building an estimator by minimization the estimation variance has been well known to statisticians since the works of Wiener (1950). The novelty of kriging was a practical day-to-day application of this principle in geosciences. Cressie (1990) gives a detailed discussion of the historical development of kriging, not only in geostatistics but also within other scientific disciplines, and proposes three key components of kriging: (i) the variable of interest is interpreted as a realization of a second-order random field; (ii) the mean is estimated (ordinary kriging and universal kriging) rather than assumed to be known (simple kriging); and (iii) the covariance function, or the variogram, is known and used to compute the kriging weights. In other words, kriging is a spatial best linear unbiased predictor.

Linear Geostatistics

The theory of kriging as it is usually presented appears in (Matheron 1962, 2019): a natural variable (e.g., a grade) distributed in space and whose behavior presents a large complexity of detail is interpreted as a realization of a random function. The regionalized variable and its random model are noted, respectively, $z(x)$ and $Z(x)$, where x denotes a point in a d -dimensional space, with d generally equal to 2 or 3. The aim

of kriging is to predict the target z_0 , which is the value $z(x_0)$ of the regionalized variable z at an unobserved point x_0 or more generally the average value $z(v)$ of z in a given cell or block v

$$z(v) = \frac{1}{|v|} \int_v z(x) \, dx.$$

The kriging value of z_0 given N observations of the variable at locations x_α , $\alpha = 1, 2, \dots, N$, with values $z_\alpha = z(x_\alpha)$, is by definition a weighted average of the observations

$$z_0^* = \sum_{\alpha=1}^N \lambda_\alpha z_\alpha.$$

The values of the regionalized variable are unknown, except at the data locations. The estimator properties are thus evaluated on all the possible outcomes of the random model in order to take into account the uncertainties resulting from a partial observation of the actual phenomenon. Later on, the kriging estimator or predictor is expressed in terms of the probability model

$$Z_0^* = \sum_{\alpha=1}^N \lambda_\alpha Z_\alpha.$$

Working in the framework of a second-order random function model, the random field is characterized by the mean (also called the drift), $m(x) = E\{Z(x)\}$, and the covariance function $C(x, x') = \text{Cov}(Z(x), Z(x'))$ or the variogram $\gamma(x, x') = \frac{1}{2}E\{(Z(x) - Z(x'))^2\}$. The weights are chosen so as to ensure that:

- The estimated value and its estimator have the same average value $E\{Z_0^* - Z_0\} = 0$ (i.e., the condition for an unbiased predictor).
- The variance of the estimation error $\text{Var}(Z_0^* - Z_0)$ be minimal (i.e., the condition for an optimal predictor).

The covariance function or the variogram is assumed known, but the stationarity of the model is not required to derive the estimators. Assumptions on the mean and the covariance function define various methods of kriging, and they have been extended in several directions. One deals with broader forms of nonstationarities (Matheron 1973; Lindgren et al. 2011), and another one considers vector-valued or even function-valued random fields (Wackernagel 2013; Menafoglio et al. 2013).

Ordinary Kriging (OK)

Ordinary kriging assumes that the mean of the random function m is constant but unknown. To ensure the unbiased condition, the kriging weights λ_α^{OK} have to sum to 1. Hence choosing the weights minimizing the variance of the estimation error $Z_0^* - Z_0$ with the condition on their sum leads to the ordinary kriging system (Chilès and Delfiner 2012, p. 163). It is a linear system of $N + 1$ equations with $N + 1$ unknowns (the N weights λ_α^{OK} and a Lagrange parameter μ)

$$\begin{cases} \sum_{\beta=1}^N \lambda_\beta^{OK} \sigma_{\alpha\beta} + \mu = \sigma_{\alpha 0} \\ \sum_{\beta=1}^N \lambda_\beta^{OK} = 1 \end{cases}$$

where $\sigma_{\alpha\beta}$ is the covariance of the observations Z_α and Z_β and $\sigma_{\alpha 0}$ is the covariance of Z_α and the target Z_0 . The variance of the estimation error, called the ordinary kriging variance, is given by the expression

$$\sigma_{OK}^2 = E\{Z_0^* - Z_0\} = \sigma_{00} - \sum_{\alpha=1}^N \lambda_\alpha^{OK} \sigma_{\alpha 0} - \mu$$

where σ_{00} is the variance of Z_0 . Because the mean m is not involved in ordinary kriging, it is possible to extend ordinary kriging to a more general random function model, the intrinsic random function model, characterized by

$$\begin{aligned} E\{Z(x+h) - Z(x)\} &= 0 \\ E\{(Z(x+h) - Z(x))^2\} &= \gamma(h) \end{aligned}$$

The variogram $\gamma(h)$ summarizes the spatial variability of the random function. Geostatistics provides a set of consistent tools for choosing the variogram model adapted to a particular situation (Chilès and Delfiner 2012). The above OK system and OK variance remain valid provided that the covariance function is formally replaced by the opposite of the variogram, $-\gamma(h)$, in the equations defining the kriging system. This is the framework where kriging is widely used, especially in mining applications.

Drifts and Residuals

Universal Kriging (UK)

The assumption of a constant mean even if unknown can be a limitation for the application of kriging to phenomena displaying a trend. However, kriging can be generalized to random functions whose drift $m(x)$ is a linear combination of deterministic known functions

$$m(x) = \sum_{l=0}^L a_l f^l(x)$$

where the a_l are unknown coefficients and the $f^l(x)$ are the $L + 1$ drift functions. The kriging estimator, renamed as universal kriging, remains of the form $Z_0^* = \sum_\alpha \lambda_\alpha^{UK} Z_\alpha$, but, because the a_l are not known, unbiasedness is ensured only under the $L + 1$ constraints

$$\sum_{\alpha=1}^N \lambda_\alpha^{UK} f_\alpha^l = f_0^l, \quad l = 0, \dots, L$$

where $f_\alpha^l = f^l(x_\alpha)$ and f_0^l is $f^l(x_0)$. The minimization of the estimation variance leads to a UK system similar to the OK system except that there are now $L + 1$ constraints instead of a single one and as many Lagrange parameters.

Simple Kriging

The simple kriging assumes that the drift of the random function, $m(x)$, is known (it can be either constant in the stationary case or any deterministic spatial function), and the unknown variable to be predicted is the residual between the field value and its mean $Z(x_0) - m(x_0)$ (when a block value is to be estimated the residual is computed with the average of the mean over a block, $Z(v) - m(v)$). The estimator of the residual is

$$(Z(x_0) - m(x_0))^* = \sum_{\alpha=1}^N \lambda_\alpha^{SK} (Z_\alpha - m_\alpha)$$

and the simple kriging estimator of the variable of interest writes

$$Z(x_0)^* = m(x_0) + \sum_{\alpha=1}^N \lambda_\alpha^{SK} (Z_\alpha - m_\alpha).$$

The condition on the mean value is fulfilled by construction, and the minimization of the estimation variance leads to the simple kriging system

$$\sum_{\beta=1}^N \lambda_\beta^{SK} \sigma_{\alpha\beta} = \sigma_{\alpha 0}$$

for $\alpha = 1, \dots, N$ and to the simple kriging variance

$$\sigma_{SK}^2 = E\{Z_0^* - Z_0\} = \sigma_{00} - \sum_{\alpha=1}^N \lambda_\alpha^{SK} \sigma_{\alpha 0}.$$

In practical applications, to know the drift is a strong assumption, hence simple kriging receives limited applications. From a theoretical point of view, however, it is important because it has nice properties not shared by ordinary or universal krigings.

Additivity Relationship

Ordinary kriging, and more generally universal kriging, provides a predictor of the target Z_0 without having to estimate the drift. However, it does implicitly estimate the drift, and it is equivalent to optimum estimation of the drift followed by a simple kriging of the residuals. For this, a similar approach of kriging can be applied to estimate the drift: a linear estimator is formed, $m^*(x_0) = \sum_{\alpha=1}^N \lambda'_\alpha Z_\alpha$, with the weights selected so that

- $E\{m^*(x_0) - m(x_0)\} = 0$ (unbiased condition).
- $Var(m^*(x_0) - m(x_0))$ is minimal (optimal condition).

The resulting system coincides with a universal kriging system in which all the covariances between the data and the target on the right-hand side of the system are null. This estimate of the drift can be regarded as generalized least squares with correlated residuals. Using this optimal estimate of the drift, m^* , universal kriging can be rewritten as

$$Z^{UK}(x_0) = m^*(x_0) + \sum_{\alpha=1}^N \lambda_\alpha^{SK} (Z(x_\alpha) - m^*(x_\alpha)).$$

The additivity relation on the kriging value extends to the kriging variance with

$$\sigma_{UK}^2 = \sigma_{SK}^2 + Var(m^*).$$

This decomposition can be exploited from a numerical point of view to efficiently solve the kriging system: the universal kriging can be expressed as simple kriging, followed by a drift correction, which appears as the solution of a linear system of $L + 1$ equations with $L + 1$ unknowns, whose matrix is positive definite. It is thus advantageous to exploit this result to solve the simple kriging system and the drift correction system both by the Cholesky method. In matrix notation, the universal kriging system is

$$\begin{Bmatrix} \Sigma & \mathbf{F} \\ \mathbf{F}^t & 0 \end{Bmatrix} \times \begin{Bmatrix} \lambda^{UK} \\ \mu \end{Bmatrix} = \begin{Bmatrix} \sigma_0 \\ f_0 \end{Bmatrix},$$

where Σ is the $N \times N$ matrix whose elements are the covariances between the observations, σ_0 is the vector of covariances between the N observations and the target, $\mathbf{F}$ is the

$N \times (L + 1)$ matrix whose (α, l) element is $f^l(x_\alpha)$, and f_0 is the vector of the $L + 1$ drift function values at the target location. Hence, the kriging system can be solved to compute the kriging weights λ^{UK} and the Lagrange parameters μ with the following procedure, which requires the resolution of two subsystems with positive definite matrices (Chilès and Delfiner 2012, p. 170):

1. Solve $\Sigma \lambda^{SK} = \sigma_0$ and $\Sigma w = F$.
2. Compute $S = F^t w$ and $R = F^t \lambda^{SK} - f_0$.
3. Solve $S \mu = R$ (S is positive definite).
4. $\lambda^{UK} = \lambda^{SK} - w \mu$.

Some Properties of Kriging

Consistency with Data Points

The kriging is an exact estimator: if the target coincides with an observation, the observed value is obviously a linear estimator, and its kriging variance is equal to zero. Thus the kriging is simply the observed value.

Smoothing Relationship

As kriging minimizes the variance of estimation error, it can be interpreted as a projection on a subset of the linear combinations of the observations fulfilling the unbiased conditions (Journel 1977). When the mean is known, the simple kriging and its kriging error are orthogonal, i.e., noncorrelated, and the Pythagorean theorem implies the smoothing relationship

$$Var(Z_0) = Var(Z_0^*) + \sigma_{SK}^2.$$

The simple kriging estimate is therefore less dispersed than the data. When the mean is unknown, the smoothing relationship can be generalized to

$$Var(Z_0 - m^*(x_0)) = Var(Z_0^* - m^*(x_0)) + \sigma_{UK}^2.$$

When observations are sparse, the estimated maps using kriging are smooth and may look unrealistic. These negative aspects of kriging have fostered the development of stochastic simulations. Incidentally, the orthogonality between the simple kriging and the estimation error is used to derive an algorithm to turn a nonconditional simulation into a conditional one.

Kriging as an Interpolator

The kriging value can be expressed as the sum of the optimal drift and a linear combination of the covariance functions (Matheron 2019)

$$Z^*(x) = \sum_{\alpha=1}^N b_{\alpha} C(x_{\alpha} - x) + \sum_{l=0}^L c_l f^l(x)$$

where the coefficients $\mathbf{b} = [b_{\alpha}]_{\alpha \in 1 : N}$ and $\mathbf{c} = [c_l]_{l \in 0 : L}$ are the solution of the dual kriging system

$$\begin{Bmatrix} \Sigma & \mathbf{F} \\ \mathbf{F}^t & 0 \end{Bmatrix} \times \begin{Bmatrix} \mathbf{b} \\ \mathbf{c} \end{Bmatrix} = \begin{Bmatrix} \mathbf{z} \\ \mathbf{0} \end{Bmatrix}$$

Block Kriging and Area-to-Point Kriging

The original development of kriging for mining aimed at estimating the average grades over the volume of selection, $Z(V)$, as the optimal linear combination of the measured grade of assays or cores, $(Z(v_{\alpha}))_{\alpha = 1, \dots, N}$. In the mining context, the support of the observations is usually constant and smaller than the support of the variable to be estimated (e.g., cores are smaller than the mining blocks); hence observations are assumed to be punctual and their covariance function, or variogram, known. In this case, the change of support from the points to block affects only the target and defines the block kriging. As kriging is a linear estimator and the transform from punctual grade to average grade is linear too, the block kriging system is very similar to the punctual kriging, only the right-hand side of the system has to be changed using the covariance values between the data points and the volume of the target

$$C_{V,\alpha} = \text{Cov}\left(Z(V), Z(x_{\alpha})\right) = \frac{1}{|V|} \int_V \text{Cov}(Z(x), Z(x_{\alpha})) dx$$

and the average value of the drift functions over the target block satisfies

$$f_V^l = \frac{1}{|V|} \int_V f^l(x) dx, \quad l = 0, \dots, L.$$

The expression of the kriging variance has to be adjusted too with the variance of the block variable. In the context of geographical applications, Kyriakidis (2004) formulates the reverse procedure of area-to-point interpolation where kriging with areal data is used to predict point values. The linear properties of kriging imply to modify only the left-hand side of the kriging system using the covariance between the observed areal data. Both are special cases of kriging where both the data and the target are defined on their own support. Kriging as a linear predictor is designed to handle such configurations if the covariance function, or the variogram, of the punctual random function is known. It only requires the computation of the average covariance between observations defined on different supports (for instance via quadrature rule)

$$\begin{aligned} C_{v_{\alpha}, v_{\beta}} &= \text{Cov}(Z(v_{\alpha}), Z(v_{\beta})) \\ &= \frac{1}{|v_{\alpha}| \times |v_{\beta}|} \int_{v_{\alpha} \times v_{\beta}} \text{Cov}(Z(x), Z(x')) dx dx' \end{aligned}$$

and the average value of the drift functions over the observation support

$$f_{v_{\alpha}}^l = \frac{1}{|v_{\alpha}|} \int_{v_{\alpha}} f^l(x) dx, \quad \alpha = 1, \dots, N.$$

Filtering with Kriging

The factorial kriging (Matheron 1982) considers an orthogonal decomposition of the variable of interest of the form $Z(x) = m(x) + \sum_k a_k Y_k(x)$, where the a_k are known coefficients and the random fields $Y_k(x)$ are orthogonal with zero mean and covariance functions C_k . In practice, the experimental variogram of the variable Z is fitted by a positive combination of covariance functions $C = \sum_k a_k^2 C_k$ with the assumption that each structure represents some heuristic factors (e.g., acquisition or processing artifacts in the case of a seismic survey). This model defines a filtering procedure extracting each factor by (co-)kriging, $Y_k^*(x_0)$, with the kriging system derived by minimizing the variance of the estimation error $\text{Var}(Y_k^*(x_0) - Y_k(x_0))$ with the no-bias condition $E\{Y_k^*(x_0)\} = 0$

$$\begin{cases} \sum_{\beta=1}^N \lambda_{\beta} C(x_{\alpha} - x_{\beta}) + \sum_{l=0}^L \mu_l f^l(x_{\alpha}) &= a_k C_k(x_0 - x_{\beta}) \\ \sum_{\beta=1}^N \lambda_{\beta} f^l(x_{\beta}) &= 0 \end{cases}$$

These kriging estimates automatically satisfy the consistency relation

$$Z^*(x_0) = m^*(x_0) + \sum_k a_k Y_k^*(x_0)$$

where $m^*(x_0)$ is the optimal estimate of the drift $m(x_0)$. This approach is commonly used to filter seismic and remote sensing surveys with multivariate data sets. A linear model of coregionalization has to be fitted using a least squares method (Desassis and Renard 2013) or via spatial factor analysis, such as min/max autocorrelation factors (Switzer and Green 1984).

Kriging for Large Data Sets

As seen in previous sections, solving the kriging system with N observations involves the inversion of a square covariance

matrix, which requires $O(N^3)$ operations and $O(N^2)$ memory. This computational intractability when N is only moderately large constitutes hurdles that geostatistics had to face since the origins of kriging, even with expensive and scarce spatial data (e.g., drill holes for mining resource or oil reserve estimations). These direct data are now usually complemented by remote sensing and indirect geophysical measurements, creating massive and heterogeneous spatial databases. As any increase of computing resources is usually balanced by some increase of the size of the data sets, strategies had to be developed in order to compute kriging in operational conditions.

Local Approach and Moving Neighborhoods

A local approach, or kriging with a moving neighborhood, was first developed, considering only a relatively small number of points that lie close to the target point. Selecting neighboring data and ignoring other data is justified in the case where these other data would have received a zero or negligible kriging weight. Sophisticated algorithms have been designed for the selection of the neighbors (Renard and Yancey 1984); these strategies try to reach a compromise between near and far sample points and data in various directions around the target location, taking into account two competing effects: the screen effect with data being screened out by the presence of closer data and the relay effect induced by the mutual correlation between data. The relay effect may be exacerbated in the case of ordinary or universal krigings, as significant weights can be attributed to data points far from the target by the implicit estimation of the drift. In such a case, when the target moves, the neighborhood moves too, and the outermost data of the neighborhood may suddenly leave the neighborhood. This is likely to create discontinuities, in particular when the dropped value is extreme. Modification of the kriging system has been proposed to ensure the continuity with moving neighborhood (Rivoirard and Romary 2011). However large data sets allow for complex and nonstationary modeling, whose complex correlation structure is not readily captured by a local neighborhood. Therefore, specific geostatistical methods have been developed for global analysis of large data sets.

Global Approach

Global approaches either approximate or select a covariance model so that computations be tractable. They rely on sparse representation of the covariance matrix or of its inverse, the precision matrix. Once the kriging system is sparse, it can be solved using the efficient algorithms of the sparse linear algebra. A first option to make the covariance matrix sparse is the covariance tapering introduced by Furrer et al. (2006). The initial covariance function is tapered beyond a certain range using a positive definite but compactly supported

function, introducing a lot of zeros into the kriging matrix. The kriging predictor can then be calculated efficiently using sparse matrix inversion algorithms. Another option to reduce this complexity is the low-rank kriging proposed by Cressie and Johannesson (2008). It represents $Z(x)$ as a linear combination of L given basis functions $f^l(x)$ with random coefficients η_l , plus a white noise $\varepsilon(x)$, whose constant variance equals to σ^2

$$Z(x) = \sum_{l=1}^L \eta_l f^l(x) + \varepsilon(x).$$

The basic functions are usually chosen so as to represent several scales of variation and, for each scale, to cover the whole study domain. Denoting by $\mathbf{F}$ the $N \times L$ matrix whose (α, l) element is $f^l(x_\alpha)$, by Σ_0 the covariance matrix of the random coefficients η_l , the covariance matrix of the kriging system is

$$\Sigma = \sigma^2 \mathbf{I} + \mathbf{F} \Sigma_0 \mathbf{F}'$$

It can be inverted using the Woodbury matrix identity

$$\Sigma^{-1} = \frac{1}{\sigma^2} \left[\mathbf{I} - \frac{1}{\sigma^2} \mathbf{F} \left(\Sigma_0^{-1} + \frac{1}{\sigma^2} \mathbf{F}' \mathbf{F} \right)^{-1} \mathbf{F}' \right].$$

Within this model, kriging becomes tractable even with a very large number of data.

Finally the Markov random field approximation (Rue and Held 2005) is the opposite of that of covariance tapering in the sense that it seeks to make the inverse of the covariance matrix and not the covariance matrix itself sparse. This strategy to work directly on the precision matrix can be extended further by rephrasing the kriging problem in terms of stochastic partial differential equations.

Stochastic Partial Differential Equations (SPDE)

The SPDE framework proposed by Lindgren et al. (2011) allows to efficiently compute kriging with a very large number of observations while taking into account non-stationarities of the second-order structure. The starting point is a result of Whittle (1954) stating that a stationary random function Z with Matern covariance function can be written as the solution of the following SPDE

$$(\kappa^2 - \Delta)^{\alpha/2} Z(x) = \mathcal{W}(x)$$

where Δ is the Laplacian in $\mathbb{R}^d$, $\mathcal{W}$ is a white-noise with suitable variance, and κ^2 and α are positive values

respectively related to the scale parameter and the regularity parameter of the Matern covariance function. The principle of the SPDE approach is to compute a discretized version of the solution on the vertices of a meshing by using the finite element method. By this way, a random vector $\mathbf{Z}$ with covariance matrix Σ is obtained. Σ is a good approximation of the matrix which would be obtained by applying the covariance function to the distances between the vertices. When α is an integer, the precision matrix $Q = \Sigma^{-1}$ can directly be computed from the finite element method, and it is a very sparse matrix. By considering a meshing with vertices including the data locations, the kriging estimator at the other vertices can be obtained by the following way. Let us first consider the vector

$$\mathbf{Z} = \begin{Bmatrix} Z_T \\ Z_D \end{Bmatrix},$$

where Z_D is the sub-vector corresponding to the data locations and Z_T the one corresponding to the target ones. Σ and the associated precision matrix Q can be written by blocks:

$$\Sigma = \begin{Bmatrix} \Sigma_{TT} & \Sigma_{TD} \\ \Sigma_{DT} & \Sigma_{DD} \end{Bmatrix} \quad Q = \Sigma^{-1} = \begin{Bmatrix} Q_{TT} & Q_{TD} \\ Q_{DT} & Q_{DD} \end{Bmatrix}$$

where $\Sigma_{DD} = \text{Cov}(Z_D, Z_D)$ is the covariance matrix corresponding to the data, $\Sigma_{TD} = \Sigma_{DT}^T = \text{Cov}(Z_T, Z_D)$ are the covariances between data and targets, and $\Sigma_{TT} = \text{Cov}(Z_T, Z_T)$. With these matrix notations, simple kriging (with mean 0) is obtained by

$$Z_T^* = \Sigma_{TD} \Sigma_{DD}^{-1} Z_D,$$

which can be rewritten with the precision matrix blocks

$$Z_T^* = -Q_{TT}^{-1} Q_{TD} Z_D.$$

The kriging over the meshing can be obtained with the inversion of the sparse matrix Q_{TT} . Its size does not depend on the number of observations but only on the number of unknown vertices. This task can be efficiently performed by sparse linear algebra routines developed to solve partial differential equations. For instance, the Cholesky decomposition of Q_{TT} can be used for moderate size problems (mostly in 2D). For larger problems, the system becomes too large for direct approaches, and some iterative methods have to be used, for instance, the conjugate gradient algorithm. The nonstationary case can easily be handled by replacing the Laplacian operator Δ with the spatially varying operator $\nabla \cdot H(x) \nabla$ where ∇ is the gradient operator of $\mathbb{R}^d$ and $H(x)$ is a continuously varying

tensor taking into account the local anisotropies (Fuglstad et al. 2015). These random fields on $\mathbb{R}^d$ with locally varying anisotropies can also be interpreted as random field defined on a Riemann manifold. Finally time is becoming pervasive in geosciences applications (e.g., remote sensing provides regular snapshots, and automatic ground stations register fine resolution chronicles). From kriging's point of view, these space-time data sets combine three challenges: the modeling of the spatio-temporal dependencies, the modeling the evolution of a phenomenon with trends, and the handling of huge data sets with peculiar structures. The SPDE approach has the flexibility to handle these issues and is an active field of research (Cameletti et al. 2013).

Limitations of Kriging and Alternative Techniques

Practitioners have argued that kriging suffers from limitations, such as its smoothing effect, its sensitivity to extreme values, its inability to take into account constraints on the variables, and its weights depending only on the covariance and the data location but not on the actual observed values. From a probabilistic point of view, the conditional expectation is the optimal predictor defined for a given spatial model. As kriging computes the conditional expectation of the Gaussian field, it is optimal as long as the spatial phenomenon of interest is adequately described by such a model. In other cases (e.g., indicator or positive variables), kriging becomes less relevant. An alternate model should be considered first; then its actual conditional expectation computed. These real issues have induced fruitful developments of more advanced techniques such as nonlinear geostatistics and stochastic simulations for which kriging often remains a key ingredient.

Nonlinear Geostatistics and Multi-Gaussian Kriging

Nonlinear methods like indicator kriging, disjunctive kriging, or conditional expectation have been developed to handle heavy-tailed distributions or to map the risks to exceed a given threshold and more generally any nonlinear transform of the observed variable (Chilès and Delfiner 2012). A model widely used in practice is the transformed Gaussian model as its conditional expectation has a closed form for any transform of point or block value. The observed variable is supposed to be a transform of a stationary Gaussian field, with a null mean and a unit variance, $Z = \phi(Y)$. This model is completely specified by the anamorphosis function, ϕ , and the correlation function of the Gaussian values, $p(h) = E\{Y(x)Y(x+h)\}$. These parameters can be easily inferred from the original data when the distribution is continuous: firstly the anamorphosis function, strictly increasing, is inverted to assign to each observed value its Gaussian counterpart; then

the empirical variogram of the Gaussian variable is computed by the method of moments and then fitted with a model by nonlinear least squares.

Gaussian fields enjoy two useful and unique properties: They are stable by linear combinations (i.e., any linear combinations of the Gaussian values is a Gaussian variable), and the absence of correlation and independence is equivalent. This property implies that the simple kriging $Y^{SK}(x_0)$ and its kriging error $Y(x_0) - Y^{SK}(x_0)$, both linear combinations of Gaussian values, form a Gaussian pair without correlation, thus independent. Hence the target variable can be rewritten as the sum of two independent Gaussian fields

$$Y(x) = Y^{SK}(x) + [Y(x) - Y^{SK}(x)].$$

This decomposition is used to compute the conditional expectation, also called the multi-Gaussian kriging (Verly 1983), of any transform of the original variable, ψ . At a target point, the Gaussian variable is expressed as the sum of the kriging value and a normal residual scaled by the standard deviation of the kriging error, $Y(x_0) = Y^{SK}(x_0) + \sigma_{SK}U$. Then nonlinear predictor is calculated using the following formula (Emery 2005)

$$\{\psi \circ \phi(Y(x_0))\}^{CE} = \int_{-\infty}^{+\infty} \psi \circ \phi(Y^{SK}(x_0) + \sigma_{SK}u) g(u) du.$$

Efficient methods are available to compute the integral value such as Gauss quadrature rules or the Hermite decomposition.

Conditional Simulations

When the variable of interest T is a nonlinear functional of the random field $\phi(Y)$ over the domain (e.g., the maximum of the field in an area, the volume of a component connected to a point, or the probability that the average over a block exceeds a threshold), the conditional expectation is still the optimal predictor, but it has generally not a closed form. However, it can be approximated by the mean of evaluations of the functional over a set of conditional simulations

$$\{T \circ \phi(Y)\}^{CE} \approx \frac{1}{N} \sum_{i=1}^N T \circ \phi(Y^{(i)}),$$

where $(Y^{(i)})_{0 < i \leq N}$ are conditional simulations of the Gaussian random field. To compute these conditional simulations, the orthogonal decomposition of the field proposed above is used to transform nonconditional simulations $\tilde{Y}^{(i)}$ of the Gaussian

field into conditional ones, by adding to the nonconditional simulation the simple kriging of the discrepancy at the conditioning points (Chilès and Delfiner 2012, p. 495)

$$Y^{(i)}(x) \equiv \tilde{Y}^{(i)}(x) + \sum_{\alpha} \lambda_{\alpha}^{SK} [Y(x_{\alpha}) - \tilde{Y}^{(i)}(x_{\alpha})].$$

Conclusions

Kriging is an optimal linear estimator that aims at estimating the value of a regionalized variable, either at a punctual location or over a larger support such as a block or a domain (Cressie 1991; Chilès and Delfiner 2012). The kriged value at a target point is a weighted average of the data values. The kriging weights are computed by solving the kriging system which takes into account the spatial continuity of the phenomenon (modeled by a covariance function or a variogram) and the relative location of the observation and the target. Kriging is unbiased and optimal and provides a measure of the accuracy of its predicted value.

Since Krige's initial regression, which took into account a local average grade and a global one to avoid bias in the estimation of a block, kriging techniques have constantly evolved to answer to new estimation problems encountered in the numerous operational situations of geosciences. Kriging is also used as a basic ingredient for more advanced techniques to handle non-Gaussian models constrained by nonlinear observations (e.g., multi-Gaussian kriging and Monte-Carlo simulations).

Due to its simplicity, kriging is robust and flexible, and it can be extended to handle new applications. Among the recent examples, SPDE techniques are now available for global application of kriging and conditional geostatistical simulations to large data sets and nonstationary random function models; the multivariate kriging or co-kriging (Wackernagel 2013) has been extended to functional data (Menafoglio et al. 2013) in order to analyze infinite-dimensional data, such as curves, surfaces, and images; the integration of complex processes governing the spatial variability of the variable of interest can be achieved using physically informed kriging (Yang et al. 2019).

Biography

William Christian KRUMBEIN, born on 28 January 1902 in Beaver Falls, Pennsylvania, USA, died 18 August 1979 in Los Angeles. He is widely recognized as “the father of mathematical geology.”

Gaining a University of Chicago PhD degree (business administration, with one introductory geology course, 1926), Krumbein worked on insurance adjustments for a finance company. Returning to University of Chicago (1929), J Harland Bretz supervised his PhD thesis (1932) on the mechanical analysis of glacial till samples. At that time, geological science was largely descriptive, but Krumbein recognized the potential of applying business statistical methods to sediments. He advanced from instructor to associate professor at the University of Chicago (1933–1942). During World War II, he served (1942–1945) with the Beach Erosion Board, US Army Corps of Engineers (military beach-landing intelligence/planning); the Board

funded much of Krumbein's later research. Krumbein became Professor of Geology at Northwestern University (1946), being named William Deering Professor of Geological Sciences (1960), and Emeritus Professor in 1970. The University of Syracuse awarded an honorary DSc (1979).

Krumbein's early work on sediment analysis and sedimentation included mechanical analyses, sampling problems, and data representation; he introduced the important *phi* scale (logarithmic transformation) for sediment particle-size distributions. Such work was tedious and difficult with hand and electrical calculators; an early IBM360 mainframe computer, installed in Northwestern University's Astronomy Department, soon had Krumbein processing data with IBM punch cards. He (with L. L. Sloss) introduced the computer into geology with their 1958 AAPG paper "High-speed digital computers in stratigraphic and facies analysis."

Krumbein was a masterful, stimulating teacher in the small Northwestern Geology Department, where close colleagues included Dapples and Sloss. Constitutionally rejecting "conventional wisdom", Krumbein pursued innovative methods whereby geological phenomena could be expressed with mathematical rigor. He taught students to question established theories and paradigms, encouraging them to view statistics as fun. He demonstrated the many ways to gather, process, and interpret the meaning of information. Krumbein paid particular attention to appropriate sampling and to each variable's variance; students were encouraged to recognize effects of normalization, transformations, etc., on calculations by writing their own computer programs.

By the 1970s, probabilistic sampling, properties, and classification of modern and ancient sediments, process-response

models, stochastic simulation, regression analysis, Markov chains, deterministic modeling, and spatial "geostatistics" were important in his research.

Manual of Sedimentary Petrography (1938, with Pettijohn) and *Stratigraphy and Sedimentation* (1951, 1963, with Sloss) were standard textbooks for several decades; *Lithofacies Maps, an atlas . . .* (1960, with Dapples and Sloss) was a compilation of their students' research. His book *An Introduction to Statistical Models in Geology* (1965, with Graybill) confirmed Krumbein at the forefront of quantitative geology. He co-authored several papers with leading statisticians including John Tukey, Geoffrey Watson, and Graybill. Krumbein published over 140 papers dealing with sediment analysis (39 publications), stratigraphic analysis (27), and statistical methods in geology (62).

The founding meeting of IAMG (1968, Prague) named Krumbein its Past President. The Krumbein Medal, IAMG's premier award initiated in 1976, is awarded annually for career achievement of a senior scientist.

Definition

Several physical phenomena, such as heat conduction and wave propagation, are modeled as ordinary and partial differential equations (ODEs and PDEs), along with initial and boundary conditions. These equations are usually differentiated with respect to time and have several approaches for finding its solutions. Laplace transform is one such tool that is available for solving these equations (Spiegel 1965; Schiff 1999). If $F(t)$ is a function of time t , such that $t > 0$, then the Laplace transform of a real values function $F(t)$ is given by $\mathcal{L}(F(t))$, which is given by:

$$\mathcal{L}(F(t)) = f(s) = \lim_{\tau \rightarrow \infty} \int_{t=0}^{\tau} e^{-st} \cdot F(t) \cdot dt, \text{ for parameter } s \in \mathbb{R}.$$

If $F(t)$ is a complex-valued function, then s is complex. The Laplace transform $\mathcal{L}(F(t))$ exists if and only if the limit of the integral exists. If the limit exists, then the integral is said to converge, and in the absence of the limit, the integral is said to diverge. The integral is the ordinary Riemann improper integral (Schiff 1999). The Laplace inverse transform on $f(s)$ gives back the original function. As an example, for $F(t) = t$ for $t > 0$, its Laplace transform is $f(s) = \frac{1}{s^2}$, where $s > 0$, and thus, the Laplace inverse of $f(s) = \frac{1}{s^2}$ is $F(t) = t$, as shown in Fig. 1. If $s \leq 0$, then the integral diverges. Thus, Laplace transformation, denoted by the symbol $\mathcal{L}$, is a map applied to a function $F(t)$ to generate a new function $f(s)$, and the same is applicable to its inverse, $\mathcal{L}^{-1}$.

Theorem 1 If $F(t)$ is piecewise continuous on $[0, \infty)$ and of exponential form with order α , then the transform $\mathcal{L}(F(t))$ exists for $\text{Re}(s) > \alpha$ and the integral converges.

For example, $\mathcal{L}(e^{\alpha \cdot t}) = \frac{1}{(s-\alpha)}$, where $\text{Re}(s) > \alpha$. Thus, this theorem defines the class of functions, L , with existing Laplace transform (Schiff 1999).

Some of the useful properties of Laplace transform include:

- **Linearity:** If $F_1 \in L$ for $\text{Re}(s) > \alpha$, and $F_2 \in L$ for $\text{Re}(s) > \beta$, then $F_1 + F_2 \in L$ for $\text{Re}(s) > \max(\alpha, \beta)$, and $\mathcal{L}(c_1 F_1(t) + c_2 F_2(t)) = c_1 \mathcal{L}(F_1(t)) + c_2 \mathcal{L}(F_2(t))$, for constants c_1 and c_2 .
- **Infinite Series:** The Laplace transform of an infinite series in t can be done term-by-term computation if the series converges for $t \geq 0$, exponential order $\alpha > 0$, and a constant term $K > 0$, where the coefficients of the powers of t in the power series have absolute values, given by $|a_n| \leq \frac{K \alpha^n}{n!}$.
- **Uniform Convergence:** For functions in L , the integral in Laplace transform converges uniformly.
- **Translation Property:** Also, known as shifting property, the first and second translations imply that shifting in the time domain (t) or Laplace domain (s), provides *closed form* solutions. For $\mathcal{L}(F(t)) = f(s)$:

$$\text{First translation : } \mathcal{L}(e^{\alpha \cdot t} F(t)) = f(s - \alpha).$$

$$\begin{aligned} \text{Second translation : } \mathcal{L}(G(t)) \\ &= e^{-\alpha \cdot s} f(s), \text{ where } G(t) \\ &= \begin{cases} F(t - \alpha), & \text{if } t > \alpha \\ 0, & \text{if } t < \alpha \end{cases} \end{aligned}$$

- **Differentiation and Integration:** There exist analytical solutions of derivatives of functions using its Laplace

Laplace Transform, Fig. 1 The Laplace transform of $F(t) = t$ and its inverse, as shown on an online tool for computing Fourier-Laplace transforms on the WIMS (WWW Interactive Multipurpose Server),

transforms and, similarly, of integrals using its inverse Laplace transforms.

- **Change of Scale Property:** The analytical solutions for scalar multiplication of the functions give the following Laplace transform, i.e., if $\mathcal{L}(F(t)) = f(s)$, then:

$$\mathcal{L}(F(\alpha \cdot t)) = \frac{1}{\alpha} f\left(\frac{s}{\alpha}\right).$$

For a more exhaustive list of properties, the textbooks on Laplace theorem (Spiegel 1965; Schiff 1999) are highly recommended references. The direct or inverse Laplace transforms of some of the special functions have closed form solutions. Such special functions include Gamma function (Γ), Bessel function of order n (J_n), Heaviside's unit step function (U), Dirac delta function, or unit impulse function (δ).

Laplace transform can be seen similar to Fourier transform, in the context of transforming signals in the time domain into a different domain. It can also have overlap with Z-transform, where the one-sided Z-transform and the Laplace transform of an ideally sampled signal are equivalent, when substituting $z \stackrel{\text{def}}{=} e^{sT}$, where s is the Laplace variable, $T = \frac{1}{f_s}$, where f_s is the sampling frequency. Additionally, the Laplace transform can be extended and unified with

authored by Gang Xiao (1999). (Image source: <https://wims.univ-cotedazur.fr/wims>)

Z-transform, which has potential applications with higher-order linear dynamic equations (Bohner and Peterson 2002).

Overview

The history of the modern Laplace transform is known to be not too old, as it started in 1937 with Bateman using it in 1910 and then was popularized by Bernstein and Doetsch in the 1920s and 1930s (Deakin 1992). The modern method was formalized in 1937, but prior to that, it was known as *Heaviside operational calculus*. The older *Laplace transformation* is closely related to Laplace transform and was then considered a solution to the PDE, $t.X''(t) - t.X'(t) + X(t) = 0$. Heaviside calculus was popular among electrical engineers, and Heaviside was a contemporary of Koppelman and Boole. The Laplace transformation itself was introduced by Euler and then used and studied by Laplace, Abel, and Poincaré. In 1937 and later, the modern Laplace transform slowly replaced the Laplace transformation, when the solutions to the aforementioned PDE began to be used in the integral form, $X(t) = \int_C e^{st} x_1(s) ds$ for $x_1(s) = a.s^{-2}$. Unlike

the earlier solutions, which used fixed limits and precomputed tables, the new solution allowed for the application/problem to define the contour C in the integral equation.

In practice, there are several numerical methods used for Laplace inversion (Davies and Martin 1979). There are broadly five classes of methods, namely, one which (i) computes a sample, (ii) expands $F(t)$ in exponential functions, (iii) uses Gaussian quadrature, (iv) uses bilinear transformation, and (v) uses Fourier series. In (i), there are methods such as Widder and Gaver-Stehfast. In (ii), methods using Legendre polynomials, trigonometric functions, and methods by Bellman et al. and Schapery are included. In (iii), Piessens' Gaussian quadrature and Schmittroth's methods are considered. In (iv), methods by Laguerre-Weeks, Laguerre-Piessens-Branders, and Chebyshev are included. In (v), methods by Dubner-Abate, Silverberg-Durbin, and Crump are included. In current practice, these methods are included in several mathematical packages, e.g., Mathematica.

Applications

There are several applications where the Laplace operator is used in geoscientific modeling and analysis. As an example, in differential geometry, generalizations of Laplace operator are widely used, such as Laplace-Beltrami operator and Laplace-de Rham operator. Each generalization has applications of its own, e.g., Laplace-Beltrami operator is widely used for shape analysis in computational geometry, for any twice-differentiable real-valued function in Euclidean space. The Laplace-Beltrami operator can be applied as the divergence of covariant tensor derivative and hence can be used on second-order tensor fields, such as stress, strain, etc., commonly used in geological or geophysical applications (Ken-Ichi 1984). Yet another example is in the use of waveform inversion using Laplace-transformed wavefields to delineate structures of the Earth, in three-dimensional (3D) seismic inversion (Shin and Cha 2008).

In practice, a class of applications where the Laplace operator is widely used is in hydrological flows (Chen et al. 2003). For convergent flows, say for that in sand and gravel aquifer, Laplace transformed power series is used for solving the radially scale-dependent advection-dispersion equation (Chen et al. 2003). Advection-dispersion equation is a special case of advection-dispersion-reaction (ADR) equation. ADR equation is used as a transport model, e.g., contaminant transport in groundwater, where the advection part of the PDE models the bulk movement of the solute (contaminant) in the flow, the dispersion part models the spreading of the solute, and the reaction part models changes in the solute mass owing to biotic and abiotic processes. In groundwater flow modeling, inverse Laplace transform has been routinely used for studying the late-time behavior of the hydraulic head in the flow (Mathias and Zimmerman 2003). In shallow water equations, Laplace inversion has been used in a contour integral to simulate low-frequency components and at the same time,

denoise, i.e., eliminate high-frequency components in advection flow in atmospheric waves, such as Kelvin waves (Clancy and Lynch 2011).

Conclusions

In summary, several physical phenomena require Laplace transforms and their inversions for their modeling, simulation, and analysis. Hence, it continues to be a powerful tool used in geoscientific applications, even in conjunction with modern deep learning solutions.

Least Absolute Deviation

A. Erhan Tercan

Department of Mining Engineering, Hacettepe University, Ankara, Turkey

Synonyms

L1-norm; Least Absolute Error; Least Absolute Value; Minimum Sum of Absolute Errors

Definition

Least absolute deviation (LAD) is an optimization criterion based on minimization of sum of absolute deviations between observed and predicted values.

The following sections discuss the problem within the scope of estimation. Let x_{ik} be the i th observation on the k th independent variable for $i = 1, \dots, n$ and $k = 1, \dots, p$ and y_i be the i th value of the dependent variable. We want to find a function f such that $f(x_{i1}, x_{i2}, \dots, x_{ip}) = y_i$. To attain this objective, suppose that the function f is of the linear form

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_p x_{ip} + \varepsilon_i \quad (1)$$

where $\beta_0, \beta_1, \beta_2, \dots, \beta_p$ are parameters whose values are not known but which we would like to estimate and ε_i is the random disturbance. We now seek estimated values of the unknown parameters, denoted by $b_0, b_1, b_2, \dots, b_p$ that minimize the sum of the absolute values of the residuals

$$\sum_{i=1}^n |e_i| = \sum_{i=1}^n |y_i - \hat{y}_i| \quad (2)$$

where $\hat{y}_i = b_0 + b_1 x_{i1} + b_2 x_{i2} + \dots + b_p x_{ip}$ is the i th predicted value, n is the number of observations, and p is the number of the independent variables.

This type of minimization problem can arise in many fields of science and engineering, including regression analysis, function approximation, signal processing, image restoration, parameter estimation, filter design, robot control, and speech enhancement.

LAD estimation is commonly used in regression analysis as an alternative measure to least squares deviation (LSD) that uses minimum sum of squared errors. It is more attractive than LSD when the errors follow non-Gaussian distributions with longer tails.

Historical Material

Roger Joseph Boscovich introduced LAD criterion in 1757 to attempt to reconcile inconsistent measurements for the purpose of estimating the shape of the Earth. Surprisingly, it was nearly a half-century before Legendre published his “Principle of Least Squares” in 1805 (Farebrother 1999). Computational difficulties associated with LAD effectively prevented its use until the second half of the twentieth century. Charnes et al. (1955) indicated that solving least absolute deviation problem is essentially equivalent to solving a linear programming problem via the simplex method. This was probably the birth of automated LAD fitting

(Bloomfield and Steiger, 1983). Starting in 1987 a number of congresses were dedicated to the problems related to least absolute deviation, and the last one was held in 2002 (Dodge 2002).

LAD did not attract Earth scientists very much due to computational and theoretical difficulties. Dougherty and Smith (1966) proposed the use of a simple trend surface method in which the sum of absolute values of deviations is minimized. While looking for resistant and robust methods of kriging, Henley (1981) devoted his book to robust methods of spatial estimation and suggested a kriging estimator based on the minimization of absolute error. As a linear estimator, kriging minimizes squared difference (error) between true and estimated value and therefore is not resistant to outliers. Dowd (1984) discussed several resistant kriging methods, reviewed robust and resistant variogram estimations, and introduced alternative methods. It is well known that the traditional estimator of the variogram is neither robust nor resistant. Walker and Loftis (1997) developed a median-type estimator based on distance-weighted LAD regression, minimizing the sum of absolute errors to optimally fit a polynomial regression to the observations.

Essential Concepts and Applications in More Detail

When $p = 0$, Eq. 2 is reduced to minimization of $\sum_{i=1}^n |y_i - b_0|$ so that the optimal value of b_0 is the median of the values y_i , $i = 1, \dots, n$. For the same estimation problem but with LSD, the solution for b_0 is the arithmetic mean of the values of the dependent variable. It is easy to see that for an even number m of the values, the optimum value of b_0 for LAD lies anywhere between the two central values of y_i . Thus, the minimization of Eq. 2 with $p = 0$ often leads to an infinity of solutions. In contrast, LSD produces unique solutions.

When $p \geq 1$, there are no simple formulas for minimization of Eq. 2 because it is non-differentiable. On the other hand, it is well known that it can be transformed into solving the linear programming problem as follows:

$$\text{Minimize } \sum_{i=1}^n (a_i + z_i) \quad (3)$$

subject to

$$b_0 + b_1 x_{i1} + b_2 x_{i2} + \dots + b_p x_{ip} + z_i - a_i = y_i$$

$$a_i \geq 0, z_i \geq 0, i = 1, \dots, n$$

Least Absolute Deviation, Table 1 The assay data for 12 samples collected from the iron deposit

K ₂ O (%)	4.50	2.11	1.44	3.30	2.99	2.32	1.55	3.21	1.10	2.40	2.65	2.41
CaO (%)	10.50	7.00	3.53	8.92	7.21	7.81	11.65	6.99	4.20	4.10	7.85	5.64

Least Absolute Deviation, Fig. 1 Scatter plot of K₂O versus CaO for assay data from the iron deposit. The fitted LAD line (solid) is $\text{CaO} = 1.85 \times \text{K}_2\text{O} + 2.16$, while it is $\text{CaO} = 1.27 \times \text{K}_2\text{O} + 3.94$ for LSD (dashed)

where a_i and z_i are, respectively, the positive and negative deviation associated with the i th observation (Armstrong and Kung 1978). This problem can be solved by the simplex method.

To illustrate the method, consider the data in Table 1 representing the variation of K₂O and CaO for 12 samples from a volcanic syn-sedimentary iron deposit.

Assume that K₂O is the independent variable and CaO is the dependent variable. Figure 1 shows a scatter plot of K₂O versus CaO together with the LAD and the LSD lines. In the plot, the solid line is the LAD fit to the data, while the dashed line is for the LSD fit. The intercept and the slope for LAD are $b_0=2.16$ and $b_1=1.85$, respectively. The LAD line was computed using the algorithm given in Armstrong and Kung (1978).

Note that the data contains an outlier at the point (1.55% K₂O, 11.65% CaO). As long as a sample remains on the same side of the LAD line, the estimates, b_0 and b_1 , do not change. This is obviously not the case for LSD. LAD criterion is thus less sensitive to outliers than that LSD; the LAD estimator is called a robust estimator.

Note also that the LAD line passes through two of the data points. This is always the case produced by the LAD algorithm for a nondegenerate data set with $p = 1$. If the data set is subject to degeneracy, then the LAD line passes through more than two data points. Birkes and Dodge (1993) suggest simple solutions for such cases.

Conclusions

Least absolute deviation is a robust criterion when the deviations follow distributions that are non-normal and subject to outliers. Since the objective function based on the LAD criterion is non-differentiable, there are no formulas for its solution; instead, the iterative algorithms such as the simplex method are used. Perhaps because of these computational and theoretical difficulties, robust methods developed on the LAD criterion have not gained wide acceptance among geoscience practitioners.

Least Absolute Value

U. Radojčić¹ and Klaus Nordhausen²

¹Institute of Statistics and Mathematical Methods in Economics, TU Wien, Vienna, Austria

²Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Definition

The least absolute value (LAV) method is a statistical optimization method which has, as a minimization criterion, the absolute errors between the data and the statistic of interest. In the one sample location problem, the solution is the sample median, while in a regression context it is an alternative to the least squares regression and is also known as least absolute deviations (LAD) regression, least absolute errors (LAE) regression, or L_1 -norm regression.

Introduction

Consider a random sample $\mathbf{y} = (y_1, \dots, y_n)^\top$ of size n . When one is interested in estimating the statistic $t(\mathbf{y})$, then the least absolute value (LAV) method solves the given problem by minimizing the criterion:

$$\sum_{i=1}^n |y_i - t(\mathbf{y})| \quad \text{or} \quad \sum_{i=1}^n |e_i|,$$

with $e_i = y_i - t(\mathbf{y})$. Thus, it minimizes the sum of absolute deviations between the observed samples and the statistic. For example, in the one sample location case the solution to the given problem is the median of the given sample.

LAV is however mostly considered in a regression framework. Let $\mathbf{y}$ denote the vector of responses and $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)^\top$ be the matrix containing the p predictors for each response for the regression model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (1)$$

where $\boldsymbol{\beta}$ is the p -variate unknown vector of coefficients one needs to estimate and $\boldsymbol{\varepsilon}$ is an n -vector of random disturbances. For the estimator $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$, the residuals are defined as:

$$\mathbf{e} = (e_1, \dots, e_n)^\top = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}.$$

The least absolute value (LAV) estimator $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ minimizes thus

$$\sum_{i=1}^n |e_i|. \quad (2)$$

An early formulation of LAV dates back to R. J. Boscovich in 1757 but the form mentioned above is due to F. Y. Edgeworth who considered it in 1887 for the simple linear regression model.

LAV regression was however often overshadowed by ordinary least squares regression (OLS) which is formulated as the minimization problem:

$$\underset{\boldsymbol{\beta}}{\operatorname{argmin}} \sum_{i=1}^n e_i^2 \quad (3)$$

and thus minimizes the squared deviations which can be seen as L_2 -norm regression.

Motivation

There is a large variety of reasons why OLS regression is probably the most common regression method, one of which is widely available efficient and easy-to-use computer routines which have made the application of OLS rather effortless and inexpensive. Also, for independent and identically distributed (iid) disturbances with finite variances, the OLS has many optimality properties, while for iid Gaussian disturbances it corresponds to the maximum likelihood estimator of model (1). However, it is well known that the OLS suffers if the disturbances have heavy tails and already a single outlier can ruin the estimates completely.

The lack of robustness is due to the optimization criterion which squares the deviations and therefore tries to avoid large residual values. This might even cause outliers in the data to

Least Absolute Value, Fig. 1 Mineral dataset with OLS and LAV model regression lines when modeling zinc content versus copper content. The suspicious observation is marked in red

be masked making outlier identification, based on residuals, difficult.

Figure 1 visualizes this problem. The data shown there comes from 53 rock samples collected in Western Australia and gives the copper (Cu) and zinc (Zn) contents (in p.p. million) and can be found in the R package **RobStatTM** (Yohai et al. 2020) as the dataset **minerals**. The figure shows the OLS fit and the LAV fit and reveals that the OLS fit is much more attracted by the observation marked in red, which can be considered an outlier, than the LAV fit. Figure 2 shows the corresponding residuals for both fits and the outlier is much less extreme in the OLS residuals than in the LAV residuals.

To address the lack of robustness and efficiency of OLS in such situations, many robust regression methods have been suggested. See, for example, Maronna et al. (2018) for a general overview and Wilson (1978) for a detailed comparison of OLS and LAV. The general idea is that LAV might be preferable over OLS whenever the median would be also more appropriate than the mean for the data at hand.

Computation of LAV Estimate

One of the things that make LAV regression appealing when compared to other robust alternatives to OLS is that the LAV criterion is convex. However, although the idea of LAV

regression is as intuitive as the one of OLS, unlike the OLS cost function, the LAV cost function is not smooth, and hence the computation of LAV is not that straightforward and the explicit solution to it does not exist. Hence, an iterative approach, which is guaranteed by the convexity of the LAV cost function to converge to the (possibly not unique) global minimum, is needed to find an optimal LAV solution.

The most common approach to obtain LAV estimates is based on the fact that the optimization problem can be reformulated as a linear program. Denote for that purpose $\hat{y}_i = x_i^\top \hat{\beta}$ as the fitted values, then the optimization problem with cost function as in Eq. (2) can be stated as the linear program

$$\min_{e_i, \hat{\beta}} \sum_{i=1}^n e_i,$$

under the constraints

$$e_i \geq y_i - \hat{y}_i, \quad e_i \geq -(y_i - \hat{y}_i), \quad \text{for } i = 1, \dots, n.$$

Thus, the constraints directly yield $e_i \geq |y_i - \hat{y}_i|$, implying that the function is being minimized for $e_i = |y_i - \hat{y}_i|$, $i = 1, \dots, n$, and for the suitable choice of $\hat{\beta}$.

Hence, the LAV estimate can be obtained with one of the many techniques to solve a linear program, like, for example,

Least Absolute Value, Fig. 2 Residuals of OLS (left) and LAV (right) models of the mineral dataset when modeling zinc content versus copper content. The residual of the suspicious observation is again marked red

the well-known simplex method (Barrodale and Roberts 1974). Other approaches to obtain the LAV estimates can be based on gradient descent (Money et al. 1982) or iterated least squares approach (Armstrong et al. 1979). A detailed list of various optimization methods can be found in Dielman (2005). A property already quite early recognized for LAV regression is that there is a solution which passes through p observations. However, going through all possible hyperplanes defined by p observations to see which is the minimizer of Eq. (2) is only feasible for small sample sizes. Another property of the LAV estimator worth mentioning is that it can, as the OLS, be seen as a maximum likelihood estimator. This is the case when the disturbances in Eq. (1) follow a Laplace distribution.

To conclude, while no closed form solution for LAV regression exists, the problem is well formulated with many algorithms available and implemented, for example, in R in the packages **quantreg** (Koenker 2021) and **L1pack** (Osorio and Wolodzko 2020). Detailed comparison of the performance of the various algorithms can be found in Dielman (2005) and the references therein.

Properties of LAV Estimator

In this section, we give some of the asymptotic properties of LAV estimator $\hat{\beta}$ of β under certain “natural” assumptions. Let the vector of observations y follow model (1). Assume furthermore that the disturbances are independent and identically distributed (iid) with distribution function F and continuous

and positive density f at the median. Furthermore, assume that $\frac{1}{n} \mathbf{X}^T \mathbf{X} \rightarrow \mathbf{Q}$ for $n \rightarrow \infty$, where $\mathbf{Q}$ is a positive definite, symmetric matrix. Then

$$\sqrt{n}(\hat{\beta} - \beta) \rightarrow \mathbf{Z},$$

where $\mathbf{Z} \sim \mathcal{N}(\mathbf{0}, w^2 \mathbf{Q}^{-1})$ comes from a multivariate normal distribution and w^2/n is the asymptotic variance of the ordinary sample median of samples with distribution F , that is, $w^2 = (2f(m))^{-2}$, where m is the median of F . Moreover, under these general conditions, it has been proven that $\hat{\beta}$ is consistent for β .

This asymptotic result clearly shows that for disturbance distributions for which the median is a more efficient estimator of the location than the mean, the LAV estimator $\hat{\beta}$ of β is more efficient than the corresponding OLS estimator (Bassett and Koenker 1978).

Based on this key result it is straightforward to develop inferential tools for β . Let $\beta = (\beta_1^T, \beta_2^T)^T$, where $\beta_1 \in \mathbb{R}^{p_1}$ and $\beta_2 \in \mathbb{R}^{p_2}$, $p_1 + p_2 = p$. Consider then the tests for the nested hypothesis of the form

$$H_0 : \beta_2 = \mathbf{0};$$

- Likelihood ratio test

$$LR = 2 \frac{LAV_1 - LAV_0}{w},$$

where LAV_1 and LAV_0 are sum of absolute values of residuals obtained at the restricted and unrestricted models, respectively.

- Wald test

$$\text{WALD} = \hat{\beta}_2^\top \mathbf{D} \hat{\beta}_2 / w^2,$$

where $\hat{\beta}_2$ is the LAV estimate of β_2 and $\mathbf{D}$ is the appropriate diagonal block of $\mathbf{X}^\top \mathbf{X}$.

- Score test

$$U = \mathbf{g}_2^\top \mathbf{D} \mathbf{g}_2,$$

where $\mathbf{g}_2$ is the appropriate part of the normalized gradient of the LAV cost function, evaluated at the restricted estimate, while $\mathbf{D}$ is as discussed in the Wald test.

All three presented test statistics have, asymptotically, a chi-squared χ_{p2}^2 distribution. Unlike the score test, both the likelihood ratio and the Wald tests however require estimation of the residual scale parameter w . Details on the tests and estimation of w can be found in Dielman (2005).

Unlike most other robust alternatives to OLS, the LAV estimator possesses a number of equivariance properties. It has been proven that the LAV estimator is affine equivariant, shift and scale equivariant, and is also being equivariant to design reparameterizations. For details, see Bassett and Koenker (1978). These properties are also shared by the OLS.

LAV possess another interesting property that has been inherited from a univariate median. Namely, for regression in $\mathbb{R}^2$, the estimated LAV regression line does not change if we vary the responses, as long as they stay at the same side of the regression line. Although it is rather obvious in the case of the one-dimensional median, as nicely stated in Dasgupta and Mishra (2004), it gives us intuition to LAVs “median-type” robustness which transfers to certain insensitivity to outliers. It is obvious that this property of LAV is not being shared by OLS. However, it makes also clear that the LAV does not tolerate well outliers in the x values.

LAV Regression with Corrected Errors

Linear regression is often used to model a linear trend in the data that is serially dependent. In such cases, the disturbances in the model are correlated and the key result about the limiting distribution from above cannot be directly applied. For simplicity consider the case $(\mathbf{x}_t, y_t)$, $t = 1, \dots, n$, following model (1), where the disturbances follow an auto-regressive $AR(1)$ process:

$$\varepsilon_t = \rho \varepsilon_{t-1} + z_t,$$

where ρ , $|\rho| < 1$ is the autocorrelation coefficient and the z_t are iid random errors. There are several two-staged procedures used to correct the autocorrelation in the error terms and are commonly used in OLS regression as well. The first stage is to linearly transform the data using the autocorrelation coefficient ρ , after which the regression is done on the transformed data. The goal of the first stage is to obtain transformed data for the linear model that has uncorrelated errors. One of such two-stage procedures is Prais–Winsten (PW) (Prais and Winsten 1954). The PW transformation matrix for model (1) with disturbances from an auto-regressive $AR(1)$ process with parameter ρ can be written as:

$$\mathbf{M} = \begin{pmatrix} \sqrt{1-\rho^2} & 0 \dots & 0 & 0 \\ -\rho & 1 \dots & 0 & 0 \\ \vdots & \vdots \ddots & \vdots & \vdots \\ 0 & 0 \dots & -\rho & 1 \end{pmatrix}.$$

The first stage of PW procedure is to pre-multiply model (1) by $\mathbf{M}$ yielding

$$\mathbf{M}\mathbf{Y} = \mathbf{M}\mathbf{X}\beta + \mathbf{M}\varepsilon, \text{ i.e., } \mathbf{Y}^* = \mathbf{X}^*\beta + \varepsilon^*, \quad (4)$$

where the vector of transformed responses $\mathbf{Y}^*$ is

$$\mathbf{Y}^* = \mathbf{M}\mathbf{Y} = (\sqrt{1-\rho^2}y_1, y_2 - \rho y_1, \dots, y_n - \rho y_{n-1}),$$

and the matrix of transformed predictors (including a transformed intercept) is

$$\mathbf{X}^* = \mathbf{M}\mathbf{X} = \begin{pmatrix} \sqrt{1-\rho^2} & \sqrt{1-\rho^2}x_{1,1} & \dots & \sqrt{1-\rho^2}x_{1,p-1} \\ 1-\rho & x_{2,1} - \rho x_{1,1} & \dots & x_{2,p-1} - \rho x_{1,p-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1-\rho & x_{n,1} - \rho x_{n-1,1} & \dots & x_{n,p-1} - \rho x_{n-1,p-1} \end{pmatrix}.$$

In the transformed model (4), ε^* is the vector of uncorrelated errors. These transformations are possible due to the equivariance properties of the LVA estimator. Other two-staged methods tackle the problem of correlated errors in a similar manner. Discussion on the performance of various methods can be found in Dielman (2005).

Other Extensions of LAV

In recent datasets the dimension p is increasing dramatically, often having $p \gg n$ and then sparse solutions $\hat{\beta}$, of the regression problem, are required. Wang et al. (2007) suggested LAV Lasso which adds an L_1 penalty on the β

coefficients. It is remarkable that the LAV Lasso can be reformulated as a regular LAV regression by augmenting the predictor matrix and can therefore be solved using the regular algorithms mentioned above.

LAV regression is also sometimes called median regression as when there is only an intercept, i.e., in the one-sample problem, the estimator of the responses is the “median”. The median gives however only one view of the conditional distribution $y_i | x_i$. Quantile regression addresses these issues and can model any quantile of $y_i | x_i$, and therefore median regression is a special case of quantile regression. For a general overview of quantile regression, see, for example, Koenker (2005).

The least absolute values methodology was originally developed in a univariate framework. However, seeing the minimization criterion as a minimization of an L_1 -norm of the model residuals allows a natural generalization to multivariate problems. General overviews over multivariate L_1 -norm methods are, for example, Oja (2010) and Nordhausen and Oja (2011).

Summary

LAV is a general statistical approach, however, most known in the context of regression, where it is well developed and a serious competitor to the ordinary least squares regression. Compared to OLS it is more robust and has better efficiencies if the disturbances have a heavy-tailed distribution and is therefore, for example, recommended for Cauchy distributed disturbances and is optimal for Laplace distributed disturbances.

Least Mean Squares

Mark A. Engle

Department of Earth, Environmental and Resource Sciences,
University of Texas at El Paso, El Paso, Texas, USA

Definition

Least mean squares is a numerical algorithm that iteratively estimates ideal data-fitting parameters or weights by attempting to minimize the mean of the squared distance of the errors between each data point and the corresponding fitted estimate. The minimization of least mean squares has no analytical solution and often relies on stochastic gradient descent, optimizing the first-order derivative of the least mean squares function to incrementally adjust and update model parameters or weights towards a global minimum. Typically, least mean squares makes updates to the weights after a

randomly chosen sample or a subsample, rather than the entire batch, making it a form of adaptive learning. The method is used across a number of Earth science applications including regression and geophysical data filtering and is the basis of early machine learning methods.

Introduction

Consider a dataset composed of a real, independent variable (y) that is a function of n real, dependent variables ($\mathbf{x}$). One could assume that the relationship between y and $\mathbf{x}$ can be reasonably approximated by applying n weights ($\mathbf{w}$) to the dependent variables, such as in linear regression:

$$y = w_1x_1 + w_2x_2 + \dots + w_nx_n,$$

or in vector form:

$$y = \mathbf{w}^T \mathbf{x}_i,$$

where $i=1, \dots, n$. For a given input ($y_i, \mathbf{x}_i$), the least mean squares algorithm quantifies the goodness of fit, error, or the cost ($J(\mathbf{w})$) between y_i and predicted estimates for a given $\mathbf{w}$:

$$J(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^m (y_i - \mathbf{w}^T \mathbf{x}_i)^2.$$

The function $J(\mathbf{w})$ calculates the sum of squared errors or residuals between y_i and the predicted estimates. The set of weights $\mathbf{w}$ that produce the smallest value of the function are considered optimal. There is no analytical solution for the minimization of $J(\mathbf{w})$ so other numerical methods must be considered. While stochastic methods to find optimal solutions for $\mathbf{w}$ could be applied at this point, least mean squares often utilizes a gradient descent approach. If we make an initial guess ($\mathbf{w}_0$) for the weights $\mathbf{w}$, using either then entire dataset or a subset thereof (referred to as the training dataset), we can calculate the loss function $J(\mathbf{w})$ but would not be sure how to adjust the values of $\mathbf{w}$ for our next guess. Instead, we can calculate the gradient (∇) of the loss function and determine the direction in which $J(\mathbf{w})$ decreases (Fig. 1). With that information, we can update or generate a new guess for $\mathbf{w}$ ($\mathbf{w}_1$) which makes a step in the direction of the steepest descent of $J(\mathbf{w})$. With this new estimate for $\mathbf{w}$, we can calculate a new $\nabla J(\mathbf{w})$, determine the direction of the steepest gradient, and take the step in this direction to generate yet another updated estimate of $\mathbf{w}$ ($\mathbf{w}_2$). Thus, the general algorithm goes through the following steps:

1. Select an initial estimate for $\mathbf{w}$.
2. Determine the value of the loss function $J(\mathbf{w})$, given $\mathbf{w}$ and the complete set, a subset, or a single random sample drawn from $y, \mathbf{x}$.

Least Mean Squares, Fig. 1 Gradient descent method for approaching the least mean squares (smallest value of $J(\mathbf{w})$) by taking steps in the opposite direction of the gradient $\nabla J(\mathbf{w})$ to provide updated weights.

3. If $J(\mathbf{w})$ is smaller than the convergence criteria, stop and accept the current values for $\mathbf{w}$ as estimates of the optimal solution. Else, move to step 4.
4. Calculate $\nabla J(\mathbf{w})$ using the current estimate of $\mathbf{w}$ ($\mathbf{w}^t$), and create an updated guess ($\mathbf{w}^{t+1}$), based upon a learning rate constant r :

$$\mathbf{w}^{t+1} = \mathbf{w}^t - r \nabla J(\mathbf{w}^t)$$

5. Start back at step 2

The $\nabla J(\mathbf{w})$ function has the form:

$$\nabla J(\mathbf{w}^t) = \left[\frac{\partial J}{\partial w_1}, \frac{\partial J}{\partial w_2}, \dots, \frac{\partial J}{\partial w_n} \right].$$

The partial differential of the least squares algorithm is solvable, allowing for calculation of the elements of $\nabla J(\mathbf{w}^t)$:

$$\frac{\partial J}{\partial w_j} = \frac{1}{2} \sum_{i=1}^m \frac{\partial}{\partial w_j} (y_i - \mathbf{w}^T \mathbf{x}_i)^2.$$

After application of the chain rule and algebra, the equation simplifies to:

$$\frac{\partial J}{\partial w_j} = - \sum_{i=1}^m (y_i - \mathbf{w}^T \mathbf{x}_i) x_{ij},$$

which represents the sum of the products of residual between y_i and the predicted value based on $\mathbf{w}^t$ and the complete set or a subset of $\mathbf{x}$. Thus, while there is no analytical solution to minimize the loss least mean squares function directly, there is an analytical solution of its gradient.

The learning rate r is generally chosen to be a relatively small constant. Generally, if r is chosen to be a large number, the algorithm will converge more quickly than if a small number is used because the size of the steps taken towards the steepest descent of $\nabla J(\mathbf{w})$ will be greater. Because the surface of least mean squares is a quadratic function, it is convex (no local minima) and has a global minimum value. However, if r is chosen to be very large, the iteration could repeatedly overshoot the global minimum leading to difficulty in convergence.

There are several variations in gradient descent solutions for least mean squares minimization. In a batch method the update process is only completed after gradient $\nabla J(\mathbf{w})$ has been calculated for all of the samples in the complete dataset of $y, \mathbf{x}$. At the other extreme, one can calculate $\nabla J(\mathbf{w})$ and update the weights for single, randomly selected samples of $y, \mathbf{x}$. This latter method, known as the incremental or true stochastic gradient descent, provides more accurate updates than the batch method but is numerically expensive. Many authors consider the incremental stochastic gradient descent to be synonymous with the least mean squares method. Conceptually, because the gradient of the loss function is updated after

every single individual sample is drawn, the method does not necessarily follow the steepest descent and produces a more random path towards the global minimum (Fig. 2). This approach allows for decisions about updating the weights to be made on the fly, which has implications for machine learning. A popular trade-off between the batch and incremental stochastic gradient descent methods is that of the mini-batch stochastic gradient descent, where a subset or a fraction of $y, \mathbf{x}$, is randomly drawn and the weights $\mathbf{w}$ are updated only after calculating $\nabla J(\mathbf{w})$ for the entire subset. One can conceptualize the mini-batch stochastic gradient descent as a path towards a minimum that it does not necessarily follow the steepest path, but not as circuitous as that of the incremental gradient descent.

Of note, the example discussed above examines the linear regression between a single output or independent variable (y) and one or more input or independent variables ($\mathbf{x}$). However, the least mean squares algorithm is extremely flexible and can be applied to solving higher-order relationships and/or scenarios with multiple independent variables. As discussed below, geophysical applications of least mean squares have been successful in estimating ideal solutions for nonlinear adaptive signal processing filters.

One serious consideration in the utilization of least mean squares methods is that estimates of optimal solutions can be strongly impacted by outliers and erroneous data because of the squaring of the error in the cost function. That is, highly anomalous or erroneous data can produce outsized loss values, as described for the entry on least squares. The effect of anomalous data can be further compounded when the method is solved using incremental stochastic gradient descent methods or mini-batch stochastic gradient descent with very small subsamples, as the impact of even a single significant outlier could cause $\nabla J(\mathbf{w})$ to be spurious and update the model weights to move away from a local minima. For this reason, datasets being used with least mean squares methods should be thoroughly examined in advance for errors or exceptional univariate and multivariate outliers.

Least Mean Squares, Fig. 2 Cartoon depicting steps taken that update weights $\hat{w}_0$ and $\hat{w}_1$ and corresponding reduction of $J(\mathbf{w})$ during a stochastic descent to the global minimum value. Note that the path is not necessarily the steepest descent, opposite the local gradient, but is rather an adaptive approach based on incremental analysis of input data.

Least Mean Squares as a Geophysical Data Filter

Least mean squares is a method for adaptive data filtering and has been heavily used in the application of electrical signal and geophysical data processing. In this case, the user is attempting to reproduce the effect of an unknown filter h which produces one or more output signals y based on n known input signals x . For example, one can consider a case where two input signals x_1 and x_2 , such as sine functions, are fed into an unknown linear transfer function h that produces an output signal g that is further perturbed by random noise b

Least Mean Squares,

Fig. 3 Schematic of an approach to utilize an adaptive least mean squares filter to emulate an unknown transfer function h . Taking a stochastic gradient descent of the least mean squares of the raw error has the effect of modifying the weights in the adaptive filter until it replicates the effect of h .

$$y_i = g_i + b,$$

where y represents the combination of the unknown filter output with random noise. In order to simulate or mimic the effect of h on x , we can create an auxiliary system which includes an adaptive filter $\hat{h}$ which allows for the application of variable weights w to the input signals (Fig. 3) and produces out $\hat{y}$:

$$\hat{y}_i = w^T x_i = \hat{h}(x_i).$$

We can make adjustments to w for sample i and quantify our accuracy in recreating the effect of h by comparing the least mean square error ($J(w)$) between the output of the two filters:

$$J(w) = \frac{1}{2} \sum_{i=1}^m (y_i - w^T x_i)^2,$$

where $i=1, \dots, n$. As described in the Introduction section, the method works to find optimum estimates of w from input data by determining the gradient $\nabla J(w)$ and updating the weights by moving in steps following the steepest descent of the subset of the training dataset. Assuming convergence toward the global minimum, the application of the final updated weights to the input signals should reasonably approximate the effect of the unknown transfer filter h .

One significant advantage of the least mean squares filter is that it automatically adjusts the unknown filter weights incrementally as new data are added. This has allowed for their

application in the development of automated and adaptive filters such a noise cancellation and adaptive signal equalization (Widrow and Stearns 1985).

ADALINE and Neural Networks

Widrow and Hoff (1960) presented the least mean squares algorithm as part of an adaptive linear (hence, “ADALINE”) machine that automatically classifies input patterns, including those affected by random noise. ADALINE and the similar perceptron (Rosenblatt 1958, 1962) mark early significant advances in the development of neural networks. The basic ADALINE model consists of the following steps:

1. Activate input x_i , where $i=1, \dots, n$.
2. Determine y_i from $y_i = b + w^T x_i$, where b is a random bias term, using the activated input from step 1.
3. Apply the following activation function to determine the output based on y_i :

$$f(y_i) = \begin{cases} 1 & \text{if } y_i \geq 0 \\ -1 & \text{if } y_i < 0 \end{cases}$$

4. Adjust the weights and biases as follows. If the results from step 3 (+1 or -1) does not match the correct classification ($t \in \{-1, +1\}$), update the weight and bias via:

$$w^{t+1} = w^t - r \nabla J(w^t)$$

and

$$b^{t+1} = b^t - r(t - y_i).$$

Else, update the weight and bias via:

$$\mathbf{w}^{t+1} = \mathbf{w}^t$$

and

$$b^{t+1} = b^t.$$

5. Repeat steps 1–4 using the updated weights and biases, unless the largest change in weights during learning is smaller than the specified tolerance.

Because y_i is a linear function, even in cases where $t = f(y_i)$, there is still an error and updates to the bias and weight occur, which allows for more rapid convergence of ADALINE versus the perceptron. The method was eventually updated to create multiple layers of ADALINE neurons, an early form of deep neural networks (Ridgeway 1962).

Summary

Least mean squares methods, depending on the exact method of numerical determination, are flexible tools capable of solving a broad range of problems. The ability of least mean squares algorithm to adaptively update weights as data are sequentially processed produces a useful solution to many problems, making them ideal for noise reduction and other geophysical methods. Moreover, related algorithms such as ADALINE serve as important milestones in the development of modern machine learning methods.

Least Median of Squares

Sara Taskinen and Klaus Nordhausen

Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Definition

The least median of squares (LMS) is a regression method introduced in Rousseeuw (1984) and further developed in Rousseeuw and Leroy (1987). The LMS estimator minimizes the median of the squared residuals. The method is shown to be highly robust having a breakdown point of 50% which is the highest possible. Because of this, the LMS regression method is fitted to the main bulk of the data while ignoring the rest of the data. Hence, atypical observations are easily identified. The method suffers from very low efficiency and is therefore recommended to be used primarily as an exploratory tool to identify regression outliers.

Introduction

Consider a data set consisting of n independent and identically distributed (iid) observations $(\mathbf{x}, y)$, $= 1, \dots, n$, where $\mathbf{x} = (x_1, \dots, x_p)'$ and y are the observed values of predictor variables and response variables, respectively. The data are assumed to follow a linear regression model

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \varepsilon_i,$$

where the p -vector $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)'$ contains the unknown regression coefficients to be estimated based on the data and the errors ε are iid and independent of $\mathbf{x}$.

The widely used least squares (LS) estimator for $\boldsymbol{\beta}$ was proposed in early 1800 by Gauss and Legendre (Stigler 1981). The LS estimate of $\boldsymbol{\beta}$ is the $\hat{\boldsymbol{\beta}}$ that minimizes

$$\sum_{i=1}^n r_i^2, \quad (1)$$

that is, the sum of squared residuals $r_i = y_i - \mathbf{x}_i' \hat{\boldsymbol{\beta}}$. The popularity of the estimate arises mainly from its nice computational and theoretical properties. The LS estimator has a

closed form solution and can be computed explicitly from data using simple matrix algebra. The estimator has also a desired property of being regression, scale and affine equivariant meaning that it is known how the estimate changes under different transformations of the data (Rousseeuw and Leroy 1987). If the error distribution is Gaussian, then the LS estimate is optimal. It is however well known that the LS estimator is extremely sensitive to outlying observations and even a single outlier can have a huge effect on the estimate. Notice that with outlier we mean here regression outlier, that is, an observation, $(\mathbf{x}'_i, y)$, where the relationship between $\mathbf{x}$ and y differs from that of the majority of the data. For the identification of different types of regression outliers, see Rousseeuw and Leroy (1987), for example.

To improve the LS estimator, several robust regression estimators have been proposed in the literature. Many of the proposed estimators are obtained by replacing the squared residuals by another function of the residuals. The least absolute deviation (LAD) estimator or L_1 regression estimator is obtained by minimizing the sum of the absolute values of the residuals $\sum_{i=1}^n |r_i|$, and a more general family of estimators, that is, the M -estimators minimize $\sum_{i=1}^n \rho(r_i)$, where ρ is a symmetric function ($\rho(-x) = \rho(x)$) with a unique minimum at zero (Huber 1973). Such regression estimates are robust against outliers in response variables (y 's); however, they cannot tolerate outliers in the predictors ($\mathbf{x}_i$'s). Notice also that such outliers, which are also called as "leverage points", cannot always be identified using residuals based on the methods described above as the regression estimates may be strongly affected by the outliers yielding small residual values.

Least Median of Squares Estimator

As mentioned in the previous section, a single outlier can strongly affect the estimates that are obtained by minimizing the sum of the squared residuals (or other function of the residuals). A regression estimator that is very robust against outliers in responses as well as outliers in predictors is obtained by replacing the sum in Eq. (1) with the median (Rousseeuw 1984). The least median of squares (LMS) estimator thus minimizes the median of the squared residuals

$$\text{Median}_i r_i^2. \quad (2)$$

In the case of a single predictor the solution can be interpreted as the midline between the two closest parallel lines which contain half of the data between them. In the case of an intercept only model, i.e., when just the location of the y 's is to be computed, the estimate is known as the

Shorth estimate, the midpoint of the shortest interval to contain 50% of the data. If the amount of the points outside the parallel lines is to be reduced the method is known as least α -quantile estimator (Rousseeuw and Leroy 1987). It is shown in Rousseeuw (1984) that there always exists a solution for Eq. (2). However, the objective function may have many local minima (Steele and Steiger 1986). For large p the computation requires some subsampling and may be time-consuming (Souvaine and Steele 1987; Joss and Marazzi 1990). See also a cautionary note on the instability of the LMS solution in Hettmansperger and Sheather (1992).

The LMS estimate for the regression coefficient is one of the few robust estimates which does not need an initial scale estimate. The same property holds for the LS estimate. Based on the LMS estimate the scale of the residuals ε can be estimated as follows. First an initial scale s_0 is obtained as

$$s_0 = 1.4826 \left(1 + \frac{5}{n-p} \right) \sqrt{\text{Median}_i r_i^2},$$

where the first constant term is for achieving consistency in case the errors follow a Gaussian distribution, and the second constant term is a finite sample correction. The initial scale is then used to define the standardized residuals $r_{st} = r/s_0$, $= 1, \dots, n$. A general rule is that observations which have absolute standardized residuals smaller than 2.5 are considered as good data points. The actual scale based on LMS, σ_{LMS} , is then the standard deviation of the (unstandardized) residuals of the good data points.

Often in robustness studies it is of interest to evaluate what is the amount of outliers the estimator can handle. To formalize this, we need a notion of breakdown point. In the next we shortly recall the definition of finite-sample breakdown point as introduced by Donoho and Huber (1983). Let a sample of n data points be $\mathbf{Z} = (\mathbf{z}_1, \dots, \mathbf{z}_n)$, where $\mathbf{z} = (\mathbf{x}', y)'$, and write $\hat{\boldsymbol{\beta}}(\mathbf{Z})$ for an regression estimate based on the data. Now consider all possible contaminated samples $\mathbf{Z}'$ that are obtained by replacing any m of the original data points by arbitrary values. Then denote the maximum bias caused by such contamination as

$$\text{bias}(m; \hat{\boldsymbol{\beta}}, \mathbf{Z}) = \sup_{\mathbf{Z}'} \|\hat{\boldsymbol{\beta}}(\mathbf{Z}') - \hat{\boldsymbol{\beta}}(\mathbf{Z})\|.$$

Infinite bias means that m outliers can have an arbitrarily large effect on $\hat{\boldsymbol{\beta}}$ and we say that the estimator "breaks down". Further, the finite-sample breakdown point is the minimum fraction of contamination that will make the estimator to break down. Mathematically, this can be expressed as

$$\varepsilon^*(\hat{\boldsymbol{\beta}}, \mathbf{Z}) = \min_{1 \leq m \leq n} \left\{ \frac{m}{n} : \text{bias}(m; \hat{\boldsymbol{\beta}}, \mathbf{Z}) = \infty \right\}.$$

Rousseeuw (1984) showed that if $p > 1$ and the observations are in general position, meaning that any p observations give a unique determination of β , then the finite sample breakdown point of the LMS estimator is $([n/2] - p + 2)/n$, where $[n/2]$ denotes the largest integer less than or equal to $n/2$. When considering the limit $n \rightarrow \infty$ (with p fixed), the asymptotic breakdown point of the LMS estimator is 50%,

Least Median of Squares, Fig. 1 Zinc and copper contents of 53 samples of rocks and the regression lines based on least median of squares regression (LMS) and least squares regression (LS) applied to the original data and data with observation 15 as rejected. The grey area around the LMS regression line contains the “inner” 50% of the data points

that is, the best one can expect. The LMS thus extends the 50% breakdown property of the median to the regression setting. Another tool to study the robustness properties of an estimator is the influence function which measures the change of the estimator when an outlying observation is introduced. As the LMS estimator converges at the rate of $n^{-1/3}$ and does not have a normal limiting distribution, its influence function is not well-defined and the estimator suffers from low efficiency. Hence, Rousseeuw (1984) recommends that LMS should not be used for inferential purposes, but as an exploratory tool for diagnosing regression outliers. LMS is for example implemented in the R package MASS (Venables and Ripley 2002) as the function `lmsrob`.

Example

Smith et al. (1984) measured the chemical contents of 53 samples of rocks in Western Australia. The data are available as the mineral data set in R (R Core Team 2020) package `RobStatTM` accompanying the book by Maronna et al. (2018). In Fig. 1 we plot the chemical contents (in parts per million) of zinc vs. the chemical contents of copper. We notice that the observation 15 stands out as a clear outlier and the LS estimator is highly influence by this observation. If we reject observation 15, then the LS fit seems to model correctly the main bulk of the data. In Fig. 2 the scaled residuals based on the LS fit are plotted. As the observations with absolute value of standardized residual exceeding 2.5 are identified as outliers (Rousseeuw and Leroy 1987), the horizontal lines at 2.5

Least Median of Squares, Fig. 2 Scaled residuals based on LS regression (left) and LMS regression (right) applied to mineral data. An observation with an absolute value of standardized residual larger than 2.5 is identified as an outlier and marked using filled black dots

and -2.5 are also added in the figure. The plot indicates that all scaled residuals are very small and although the LS method reveals two outliers, none of them is classified extremely atypical.

The LMS estimator is not affected by observation 15 and the resulting fit is nearly equivalent to the LS fit obtained when the observation 15 is rejected. The LMS estimates for intercept and slope are 11.79 and 0.06, respectively (as compared to the LS estimates 7.96 and 0.13). The scaled residuals in Fig. 2 indicate that the method identifies altogether eight outliers and observation 15 clearly stands out in the residual plot.

To have an idea about the model fit, Rousseeuw and Leroy (1987) define the coefficient of determination in the case of LMS as

$$R_{LMS}^2 = 1 - \left(\frac{\text{Median}_i |r_i|}{\text{Mad}_i y_i} \right)^2,$$

where $\text{Mad } y$ denotes the median absolute deviation. For our example data $R_{LMS}^2 = 0.59$ which is much better than the regular coefficient of determination of the LS fit of $R_{LS}^2 = 0.46$.

Finally notice that in this simple example it was easy to identify an outlier just by plotting the data. However, outlier identification becomes more difficult when the number of predictors increase and cannot be performed just by plotting the data. In such a case one should proceed as guided in Rousseeuw and Leroy (1987), for example.

Summary and Conclusion

The paper introducing the LMS Rousseeuw and Leroy (1987) is considered as a seminal paper in the development of robust statistics and is, for example, appreciated in the Breakthroughs in Statistics series (Kotz and Johnson 1997). LMS demonstrates that high breakdown regression can be performed with outliers present in response and predictors. However, due to its low efficiency and the development of better robust regression methods such as MM-regression (Yohai 1987), LMS is nowadays mainly used for exploratory data analysis and as an initial estimate for more sophisticated methods.

Least Squares

Mark A. Engle

Department of Geological Sciences, University of Texas at El Paso, El Paso, TX, USA

Definition

Least squares is a numerical method to estimate ideal solutions for model fit parameters in overdetermined systems by minimizing the sum of squares distance of the residuals between one or more variables for each data point and the corresponding model estimate(s). The approach only

considers uncertainty or error in the variables being used in the determination of residuals (e.g., response variables), but not in the other variables (e.g., predictor variables). The method is commonly used to approximate best-fitting solutions to both linear and nonlinear regression systems, but is also applied to more general applications including machine learning.

Introduction

Consider a set of n data points composed of one or more predictor variables (x_i) and one or more response variables (y_i), where $i = 1, \dots, n$. Myriad methods exist to determine optimal parameters for numerical models estimating values of the response variable(s) ($\hat{y}_i$) from the predictor value(s) for overfitted systems. One such method, least squares, is an efficient approach that utilizes the set of residuals or errors (e_i), defined as difference between the measured and predicted response values:

$$e_i = y_i - \hat{y}_i,$$

but can more generally refer to any variables or set of variables that the model is attempting to fit. Regardless of the exact mathematical form of the prediction model, the least squares method evaluates candidates for the m model parameters (β_k), where $k = 1, \dots, m$, by calculating the sum of squares residuals or errors (SS_e) for the data set:

$$SS_e = \sum_{i=1}^n e_i^2.$$

The set of m values for β_k that produces the lowest SS_e is considered the optimal solution. A generalized solution to the minimization of SSE for any numerical systems is to set a gradient with respect to β_k equal to zero:

$$\frac{\partial SS_e}{\partial \beta_k} = 0.$$

Linear Least Squares Regression

One of the oldest and most well utilized applications of least squares methods is linear least squares regression, which was developed by Legendre (1805) and Gauss (1809). Linear least squares is a commonly applied method to generate linear estimates of y_i in overdetermined mathematical systems, using m number of predictor variables. The method is pervasive throughout the earth sciences and used in a broad range of topics from evaluating potential controls on geologic processes to calibrating instrumentation and numerical models. Values of y_i are modeled from linear combinations of the

m predictor variables (x_{ik}) and model parameters β_k , where $k = 1, \dots, m$ with a generalized form of:

$$y_i = \beta_0 + \beta_1 x_{i1} + \dots + \beta_m x_{im} + \varepsilon,$$

where ε represents model error or uncertainty. In the case of simple linear least squares (also called ordinary least squares), based on a single x_i , modeled values of $\hat{y}_i$ are calculated from estimates of model parameters $\hat{\beta}_0$ and $\hat{\beta}_1$:

$$\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i,$$

and the residuals are calculated as described in the “[Introduction](#)” section. As an example, let us say we want to provide rapid screening results in the field by developing a model to predict the density of water samples (typically a laboratory measurement) from their specific conductance measurements (a field measurement) for brackish groundwater samples from the Dockum aquifer in Texas, USA (data subset from Reyes et al. 2018). There exists an analytical solution for $\hat{\beta}_0$ and $\hat{\beta}_1$ in simple linear least squares regression that minimizes SS_e :

$$\hat{\beta}_1 = \frac{SS_{xy}}{SS_{xx}}$$

and

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x},$$

where

$$SS_x = \sum_{i=1}^n (x_i - \bar{x})^2$$

and

$$SS_{xy} = \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y}).$$

SS_x is the sum of squared distances between the predictor values and its mean, which if divided by the degrees of freedom of x_i is equal to its variance. Similarly, SS_{xy} is the sum of squares for the x_i and y_i cross products. The sum of squares of y_i (SS_y) can be divided into the sum of squares accounted for by the model (SS_p) versus that not explained by the model, which is equal to SS_e or the sum of squares of the residuals:

$$SS_y = SS_p + SS_e,$$

and can be further explored using Analysis of Variance (ANOVA) methods. It is then relatively intuitive to develop

Least Squares, Fig. 1 Simple linear least squares regression model to predict density from specific conductivity data for groundwater samples from the Dockum Aquifer, Texas, USA. (Data subset from Reyes et al. 2018)

an estimator of fit quality (the coefficient of determination, or R^2) calculated as portion of SS_y explained by the model:

$$R^2 = \frac{SS_p}{SS_y}.$$

Relationships between x_i , y_i , $\hat{y}_i$, and e_i , including the least squares regression line for the above example are illustrated in Fig. 1. In this case, $SS_y = 2.05 \times 10^{-4}$, $SS_p = 1.42 \times 10^{-4}$, and $SS_e = 6.32 \times 10^{-5}$, producing an R^2 value of 0.69, meaning that nearly 70% of the sum of squares in the dependent variable is accounted for by the simple linear least squares regression model. Many texts suggest that in order for a linear regression model to satisfy its mathematical assumptions, the residuals must be independent, constant across the range of predictor variables (homoscedastic), and normally distributed. In reality, however, the requirement to meet assumptions varies depending on the purpose of the linear least squares regression model. For instance, Helsel et al. (2020) argue that if the intended use of the model is simply to predict y_i from x_i , then the only requirement is that the relationship between the predictor variable(s) and the response variable is linear and that the data used in the analysis are representative. Assumptions that the residuals be normally distributed are reserved for instances of hypothesis testing or calculating confidence intervals. Depending on the final purpose of the model predicting density from specific conductance, additional investigation about the nature of the residuals may or may not be required.

Least squares solutions are used to estimate model parameters for many types of linear regression models including

linear regression, linear multivariate regression (many predictor variables and one response variable), and linear multivariable regression (many predictor and response variables). One documented problem with least squares models utilizing multiple predictor and/or response variables is that if sets of variables are strongly correlated (i.e., multicollinearity), the model results can be misleading. Methods such as stepwise, lasso, and ridge regression have been developed to determine variables most important in model prediction, and subsequently remove the remaining variables, as one method to overcome multicollinearity problems. This approach has the advantage that a more parsimonious model is generated, requiring fewer model inputs, than one utilizing all of the available variables. An alternative approach, utilized by least partial squares and principal component regression methods, is to extract latent components from the predictor variables. The latent components, which should have minimal correlation to one another, are used as predictor variables in the regression model instead of the original predictor variables. These methods make more efficient use of the data, while reducing multicollinearity and the number of parameters in the final model.

Nonlinear Least Squares Regression

Linear regression methods are most useful when the relationship between the predictor variable(s) and the response variable(s): (1) follows a hyperplane and (2) can be reasonably recreated from linear combinations of the response variables. In some cases, the relationships between the original variables is not linear but can be approximated as such by transforming one or more variables and processing the transformed data with linear methods. However, in instances where variable transformation fails to produce linear relationships between x_i and y_i , or residuals vary in a nonrandom way around x_i , nonlinear least squares regression methods can be attempted by utilizing a nonlinear prediction function $f(x, \beta)$. In nonlinear least squares regression, there is no closed form analytical solution and optimal values of regression parameters are estimated iteratively, by adjusting the m model parameters at iteration t by a known quantity ($\Delta\beta$) for the next time step ($t + 1$):

$$\beta_k^{t+1} = \beta_k^t + \Delta\beta.$$

If the model contains m predictor variables, then the goal of the iterative approach is to find model parameters β_k that produce a value of zero for the following equation:

$$\frac{\partial S}{\partial \beta_k} = -2 \sum_{i=1}^m r_i \frac{\partial f(x_i, \beta)}{\partial \beta_k} = 0.$$

The equation is numerically solved through the application of iterative convergence methods such as the Gauss-Newton and Gauss-Siedel algorithms. This generalized solution approach allows for the application of least squares model-fitting approaches to be applied to a range of other applications and models. However, unlike linear systems, solutions to nonlinear least squares models are not unique as multiple local minima can exist. Thus, there is no guarantee that solutions are optimal.

Non-regression Least Squares Methods

Least squares methods require only the ability to measure residuals between response variable(s) and their modeled values and one or more model parameters to adjust and make efficient use of the data. This makes least squares attractive for a wide range of geologic problems. Some of the earliest applications of least squares methods were fitting models to estimate the size and shape of the earth and moon and of the orbits of the planets (Nieverfelt 2000), for instance. Least squares models have also made in-roads as an efficient solution for machine learning techniques, particularly variations of support vector machines. Support vector machines are non-probabilistic supervised classification models that define classifier functions (typically pairs of hyperplanes) that best separate each defined group of data, or projected data, in the dataset. For a given training data set $\{x_k, y_k\}$, for $k = 1, \dots, l$, where x_k are real data corresponding and y_k is the group classifier ($y_k \in \{-1, +1\}$ in the case of 2 groups), if there exists no hyperplane or set of hyperplanes that can perfectly separate the data, a slack variable (ζ_k) is added to the relationship such that:

$$y_k = w^T \varphi(y_k) + b \geq 1 - \zeta_k$$

and $\zeta_k > 0$. w^T is a transformed classification vector, $\varphi(y_k)$ is nonlinear transformation of y_k into high level space created using the so-called kernel trick, and b is constant. A common method to find estimates of optimized model parameters ($\hat{w}^T$ and $\hat{b}$), which represent the hyperplane exhibiting the largest region between the groups of samples (i.e., margin) is to construct Lagrange multipliers, producing a quadratic optimization equation. Suykens and Vandewalle (1999) reformulated the problem into a least squares model producing, after utilization of Lagrange multipliers, a linear system to be solved. Least squares methods have made in-roads into other machine learning methods as well; Mao et al. (2017) applied a least squares approach to the discriminator function in generative adversarial networks to overcome the vanishing gradient problem using descent methods during learning.

Thus, despite the historic origin of the method, least squares still has utility in next generation analysis and machine learning tools.

Robust Least Squares Methods

One criticism of least squares methods is that calculating the square of the residuals, as opposed to other distance measurements, biases the results towards data points that are far away from the predicted values. Comparison of sum of squares versus absolute residual distances (as is used in L_1 linear least squares regression, which estimates the median value of y_i for a given x_i) shows that the former heavily weights points at distances when residuals are >1 while it gives relatively less weight when residuals are <1 (Fig. 2). As a result, several least squares-based robust and resistant regression techniques have been developed to reduce the impact of highly influential points. Earlier robust methods, such as Huber's M-estimator (Huber 1964), limit the distances above a specific residual threshold but do not consider errors in the predictor variables. Huber's method involves choosing a tuning parameter ranging from 0 (producing a form equivalent to L_1 regression) to ∞ (equivalent to least squares linear regression), which determines the efficiency of the method (Fig. 2). Both least squares regression and Huber's M-estimator both exhibit breakdown points of 0; even a single erroneous or problematic data point can impact the regression result. Newer sum of squares-based regression methods, such as least trimmed squares (Rousseeuw and Leroy 1987), were developed to

Least Squares, Fig. 2 Comparison of sum of squares, absolute, and Huber's M-estimator distance (using a tuning parameter of 1.345) based on residuals

adapt to outliers in both x_i and y_i and have breakdown points as high as 50%. Numerically, the objective function of least trimmed squares regression is nearly identical to linear least squares regression, except that: (1) the calculation is performed on a subset of the data (typically 50–75%) that exhibits the lowest minimum covariance determinant and (2) there exists no analytical solution. Comparison between least trimmed squares and least mean squares regression show that in instances with well-behaved data, the methods will produce nearly identical results. However, in cases where even a small proportion of outliers are present, as is common in many geological datasets, they are much more likely to have a significant impact on the optimized model parameters between the two methods, largely due to the difference in breakdown points. With improvements in computing power and optimization procedures and the similarity between models from traditional and robust methods, there is some logic in utilizing robust least squares methods as the default approach. Use of robust and resistant least squares methods, arguably, opens scientists and engineers to less potential criticism relative to an alternative approach of removing seemingly problematic points from the dataset. Work on methods to improve robust methods for least squares models and methods is continuing.

Summary

Least squares methods have been applied to a wide range of applications in the earth and planetary sciences, dating back more than two centuries. The well-studied behavior of least squares models, their efficient use of the data, and their minimal data requirements make them an attractive choice for model fitting in overdetermined systems. Though mostly known for their use in linear regression models, least squares methods have also been successfully applied in nonlinear model fitting and are finding revitalization in machine learning algorithms. Users of least squares models should be aware of the heavy weight the method places on data points with large residuals and that for some applications robust alternatives are available to prevent deleterious modeling results from erroneous or problematic data.

LiDAR

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Light Detection and Ranging (LiDAR) is a remote sensing technique which uses electromagnetic radiation, i.e., light, to measure the distance of objects of interest from the sensor. The time taken for the reflected radiation to return to the sensor gives the distance from the sensor. The reflected radiation, in comparison to the emitted radiation, loses energy during its onward and return travel. The loss in energy may be attributed to the optical properties of the material of the objects it is incident upon, as well as, the medium through which it has traveled. After normalizing for the latter, the former is useful information for semantically analyzing the acquired data, and reconstructing the region that has been scanned.

LiDAR is an active remote sensing system, as it generates energy, which is emitted in the form of light from a laser sensor at a high rate. The LiDAR instrument has a transmitter to emit light pulses, and receiver to record the reflected pulses. The distance captured from the time taken by the reflected rays is corrected using the geolocation information of the sensor. This distance is the elevation in the case of airborne

sensors or aerial laser scanners, but is the distance to the sensor in the case of terrestrial or mobile sensors, mounted on static or dynamic platforms. The GPS (global positioning system) and the IMU (internal measurement unit) in the LiDAR instrument are used for obtaining accurate positional coordinates and orientation of the instrument to find absolute position coordinates of the objects of interest. Depending on the application and type of LiDAR system used, the objects of interest include objects in the scanned scene or topography, including buildings, vehicles, vegetation, and people. The advantages of LiDAR include high-density, high-accuracy discretized point observations, useful for generating digital elevation models (DEM), and diverse applications. LiDAR technology is versatile to be used for land management, hazard assessment (e.g., flooding), forest science, ocean sciences, etc.

The measurements acquired from the LiDAR system are stored and managed as a point cloud, which is a set of position coordinates (x, y, z) from where the light pulses have been reflected. The LiDAR sensor captures the reflected light energy in two different ways, namely, the discrete returns and the full waveform systems. The discrete LiDAR records *returns*, which are points in the peaks of the waveform. Such a system can record one to four returns. However, a full waveform LiDAR system records more information through a full distribution of reflected energy. Both systems record discrete points, which are stored in .las file format. GeoTIFF formats are also used for storing LiDAR data. This data generally stores position coordinates of the three-dimensional (3D) points in the point cloud, intensity (or remission), and optionally, semantic class labels. Semantic class labels refer to the class of objects the point belong to, e.g., buildings and road in urban data.

Overview

LiDAR technology is broadly categorized as airborne (aerial laser scanning (ALS)) and terrestrial (terrestrial laser scanning (TLS)) sensors, based on its data acquisition mode. Airborne LiDAR sensors are usually used for scanning larger areas, and are carried by low flying aircrafts or unmanned aerial vehicles. Terrestrial LiDAR is collected from land, from a fixed location or when mounted on land vehicles. Terrestrial LiDAR can scan 360° views. Airborne LiDAR is apt for scanning larger spatial scales, such as regions at city-level or for coastal projects, giving a bird's eye view, in comparison to that of terrestrial LiDAR. Terrestrial laser scanning covers regions where airborne sensors cannot access, such as moving traffic, building interiors, etc. Combining airborne and terrestrial LiDAR remote sensing can provide complete details of regions of interest.

Airborne LiDAR is subclassified as topographic and bathymetric, based on its applications. Topographic LiDAR

uses near-infrared light pulses to sense the land, and bathymetric LiDAR uses green light to penetrate through volume of water to sense the sea-floor or riverbed. The former has been originally used for studying topography or structures under dense tree cover or canopy, and in mountainous regions. The topographic LiDAR has also been used for computing accurate shorelines and flood maps. The bathymetric LiDAR has been widely used for studying underwater terrains, and varied hydrographic applications. The topographic and bathymetric maps essentially are *elevation* maps.

Terrestrial LiDAR, used for scanning built-up area, are of two types – static and mobile LiDAR. Terrestrial LiDAR measures *distance* maps, which measures distances from the sensor in its 360° view. TLS scanners enable scanning above ground using fast and dense sampling. They capture data with low oblique angle of signals, and the light signals which are reflected by obstacles also include shadows in 3D point clouds. To mitigate such effects, TLS scanning is done from multiple viewpoints (Baltensweiler et al. 2017). The irregular point distribution and shadowing by obstacles introduce challenges in separation of ground and non-ground points in TLS data, more than so in ALS data.

Applications

The LiDAR point clouds are used for generating digital elevation models (DEM), and TLS data is used for digital soil mapping, among other applications (Baltensweiler et al. 2017). The term “DEM” loosely include both digital surface model (DSM) and digital terrain model (DTM), of which the latter is specific to terrains (Chen et al. 2017). The spatial resolution of the DEM generated from ALS is within 0.1–1.5 m. The root mean square errors (RMSE) of the DEMs are dependent on the site/region types, and are of the order of 0.007–0.525 m and 0.286–0.306 m for TLS and ALS, respectively, considering at to uneven slope terrains.

Coastal mapping is done extensively using LiDAR technology. This includes the use of terrestrial LiDAR to provide dry-beach DEM, and use of airborne LiDAR bathymetry for shoreline mapping by gathering data for regional coastal geomorphology and identifying shallow-water depth measurement (Irish and Lillycrop 1999). ALS data has been used for qualitative and quantitative channel dynamics in fluvial geomorphology, applicable to river catchment. The applications of ALS data also include ground filtering, building detection and reconstruction, tree classification, road detection, and semantic segmentation and classification (Lohani and Ghosh 2017).

The use of Unmanned Aerial Vehicles (UAV), such as drones, has increased in various applications, including archeological remote sensing. Similarly, the modern usage of mobile LiDAR in sensing has been used widely in autonomous driving to support data analysis for blind-spots, lane

drifting, cruise control, etc. The interest in the area of vehicle LiDAR also include the development of varied computing platforms on the edge, and in the fog and the cloud. Overall the applications of LiDAR measurements are relevant based on the spatial resolution and accuracy values.

Point Cloud Analysis: With a Focus on ALS

Airborne LiDAR or ALS point clouds include complete scans of top-view of sites, as shown in Fig. 1, which exploit geometric information for automated analysis. This geometric information is extracted using spatially local neighbors, as the LiDAR data preserves spatial locality. Such information is extracted using *local geometric descriptors*. These descriptors are defined as data that encodes the local geometric information, and are usually in the form of matrices or positive semidefinite second-order tensor fields (Sreevalsan-Nair and Kumari 2017). It is important for the matrices or second-order tensors to be positive semi-definite, as positive eigenvalues are required for further analysis. These local neighborhood are of varied shapes, depending on the application. Spherical, cylindrical, k-nearest, cubical neighborhoods are usually used.

Neighborhood search is a computationally intensive process, which can be made efficient using appropriate data structures. Octrees and kd-trees are used conventionally to partition the 3D bounding box containing the point cloud. The use of efficient hierarchical data structures reduces overall time in descriptor computation and subsequent feature extraction.

Semantic or object-based classification is a key data analytic process implemented on both ALS and TLS point

clouds. Supervised learning is largely used for ALS point clouds, where the point-wise feature vectors are hand-crafted. These features include two- and three-dimensional features, height-, and eigenvalue-based features. The feature extraction involves computation of features from local geometric descriptors using multiple spatial scales to gather more relevant information, of which an optimal scale is determined (Weinmann et al. 2015). The spatial scale considered here is the size of the local neighborhood where the optimal scale is where the entropy in the geometric classification of the point cloud is a global minimum. Depending on the relevance of the features, there are up-to 21 features, computed at the optimal scale included in the feature vector (Weinmann et al. 2015). Random forest tree classifier is best suited for the semantic classification of the LiDAR point cloud. Being a supervised learning, sufficiently large training data is required for training the model to improve classification accuracy. Detection and localization/instantiation of specific classes, such as, buildings, road/ground, etc., are well-researched topics (Sampath and Shan 2009; Chen et al. 2017).

The points can be geometrically classified as linear, planar, and volumetric features. They are alternatively called line-type, surface-type, and point/junction-type features. Combining semantic and geometric classification as a tuple of labels could be referred to as augmented semantic classification (Kumari and Sreevalsan-Nair 2015). The tuple of labels help in better graphical rendering of point clouds, where edges are delineated clearly. Larger sections of the point clouds tend to be surface-type features, as they include points on the exposed faces, interior to the object/instance boundaries. The normal to the surfaces can provide salient information. The normal information computed for multiple scales can be used to compute difference of normal (DoN) (Ioannou

LiDAR, Fig. 1 (a) Point rendering of Aerial Laser Scanned (ALS) point clouds of topographic data from Vaihingen site, Germany, using data provided by ISPRS as benchmark data. The red points are linear features, delineating structures, e.g., building roofs, and localizing objects, e.g., foliage, and gray are remaining points. (b) Corresponding orthoimage.

et al. 2012). DoN and other surface features have been effectively used for segmentation and classification.

Geometric reconstruction is another significant data analytic application implemented on point clouds. Building roof extraction is an application where points classified as building points, and localized as instances are used to reconstruct regions for graphical rendering, 3D printing, computer aided design (CAD), etc. Roof reconstruction involves finding contour lines or boundaries, and planar facets. The former can be done by using break-line extraction (Sampath and Shan 2009), Marching Triangles method on a triangulated irregular network (TIN) of points, and tensor-line extraction (Sreevalsan-Nair et al. 2018). The points can be clustered effectively to improve segmentation (Sampath and Shan 2009). Once the boundaries are extracted, one can fill in the planar facets using plane equations and geometric approximation methods of plane fitting.

Future Scope

Efficient and accurate DEM generation continues to be a problem of interest, specifically to improve the LiDAR point analysis. DTM generation can be improved by combining several related DTM generation methods (Chen et al. 2017), which is applicable to the larger set of DEMs. This involves combining different multi-scale aggregation algorithms, clustering, segmentation, classification, and geometric extraction methods. There are two approaches in combining methods. In the first approach, processes or components in the generation algorithms may be combined. In the second approach, the different outputs (DEMs) may be merged to give an improved DEM.

Another way of improving DEMs is the multimodal method, which involves inclusion of different data sources, in addition to LiDAR data. Thus, this method addresses the deficiencies in information capture and processing in LiDAR. Spectral features from aerial images, high resolution satellite imagery, high resolution photogrammatic point clouds are some of the data sources that have been successfully combined with LiDAR to extend its applications beyond DEM or DTM generation (Chen et al. 2017). Apart from the widely used discrete return LiDAR, the full-waveform LiDAR data has demonstrated strong potential for generating DTMs.

Some of the challenges faced in mobile LiDAR in data processing in the presence of high data uncertainty are handled by the use of machine learning and neural network models. However, this work requires in-depth research, as in ALS point clouds, to improve on the different classes of methodology for point cloud processing. For DTM generation using ALS, there are six different classes of methods, namely, surface-based corrections, morphological filters, TIN refinement, segmentation in conjunction with classification,

statistical analysis, and multi-scale aggregation methods. Use of the vehicle/mobile LiDAR for autonomous driving application is the latest entrant to be added to potential application of LiDAR point clouds. Geometric modeling is not directly extensible from ALS to mobile LiDAR owing to the incompleteness in scans of objects, especially of moving ones, in 360° views. Apart from bringing in variety in processing steps, efficiency is also a key requirement for edge, fog, and cloud computing that is posed to be used in autonomous driving, which is a potential use-case of interconnected network of sensors and *things*, referring to the internet of things (IoT).

In summary, LiDAR imagery in the form of 3D point clouds is an effective remote sensing method which is useful for varied applications in geoscience and GIS (geographical information systems), owing to its accuracy and sampling.

Linear Unmixing

Katherine L. Silversides

Australian Centre for Field Robotics, Rio Tinto Centre for Mining Automation, The University of Sydney, Sydney, NSW, Australia

Definition

Linear unmixing is a method of calculating the composition of a mixed sample (Weltje 1997). A geological example is when a rock sample is known to be a physical mix of certain minerals. These minerals are the endmembers. If the chemical composition of the endmembers and the sample is known, linear unmixing can be used to estimate the amount of each mineral in the sample. If the endmember minerals or their compositions are unknown, instead bilinear unmixing can be used to estimate both the endmember and sample compositions (Full 2018; Weltje 1997).

Introduction

A linear mixture occurs when endmembers are physically mixed or a sample has a composition that can be mathematically considered to be a combination of distinct endmembers with fixed compositions (Weltje 1997). An example of a linear mixture is when red and blue grains are mixed and the result is a mix of individual red and blue grains, not purple grains. When the composition of a sample and the endmembers is known, linear unmixing can be used to calculate the percentage of endmembers present in the sample. If the composition of the endmembers is unknown, the problem becomes bilinear (or explicit) unmixing. In this case, the composition of the endmembers is also estimated at the same time (Tolosana-Delgado et al. 2011; Weltje 1997).

Geological specimens or rocks can be considered to be comprised of linear mixes of endmembers, where the endmembers are a set of minerals with known chemical compositions (Weltje 1997). All of the samples are then comprised of a mixture of these endmembers. If the number of endmembers and their compositions is known, then the bulk composition of each rock can be calculated or estimated using linear unmixing (Weltje 1997). Linear mixtures are used in situations such as identifying minerals from bulk geochemistry (Renner et al. 2014; Silversides and Melkumyan 2017; Tolosana-Delgado et al. 2011; Weltje 1997) and hyperspectral data analysis (Bioucas-Dias et al. 2012; Chase and Holyer 1990; Dobigeon et al. 2009; Liu et al. 2018; van der Meer 1999).

Theory

Linear mixing can be considered as a matrix problem. The first matrix, X , contains D characteristics observed in N samples. Each sample is assumed to each be a mixture of P endmembers, where the characteristics of each composite sample are a weighted average of the endmember characteristics. The second matrix, T , is a $P \times D$ matrix that describes the characteristics of each endmember. These can be used to solve

$$X = Y \cdot T,$$

where $Y = (y_{ij})$ is a matrix containing the weights of the j th endmember in the i th sample. Solving for Y therefore provides the composition of each sample. In linear unmixing, the endmember characteristics, and therefore T , are known. In the bilinear problem, the endmember characteristics are unknown, and more complex solutions are required to solve for Y and T simultaneously (Tolosana-Delgado et al. 2011; Full 2018).

Mathematical Example

A system containing three endmembers, which are measured using four characteristics, can be described using a 3×4 matrix. For example,

$$T = \begin{bmatrix} 4 & 1 & 2 \\ 4 & 1 & 6 \\ 1 & 4 & 2 \\ 1 & 4 & 0 \end{bmatrix}$$

If there are two composite samples, they can be represented by a 4×2 matrix, for example,

$$Y = \begin{bmatrix} 1 & 1 & 4 & 4 \\ 2 & 5 & 3 & 2 \end{bmatrix}$$

These can then be used to find the weights using the equation above. Using these examples, the weights are

$$X = \begin{bmatrix} 22 & 28 & 24 \\ 33 & 27 & 40 \end{bmatrix}$$

This means that the first sample contains the endmembers in the ratio 22:28:24 and the second sample contains the endmembers in the ratio 33:27:40.

Applications

Linear unmixing can be applied to any sequence of data that contains mixtures of materials where each mixture produces observations that are a linear combination of the endmembers. Common applications include hyperspectral analysis and determining mineralogy from bulk chemistry. These are briefly discussed below.

Hyperspectral cameras or sensors can be used in geoscience applications to determine the proportion of materials such as minerals. These sensors measure electromagnetic energy across numerous wavelengths. In the geosciences, bands covering the visible, near-infrared, and shortwave infrared spectral bands are frequently used. The signal or spectrum recorded by a hyperspectral sensor is a result of the light reflected by the objects located in its field of view. Spectroscopic analysis can then be used to determine the composition of these objects. In mineral scanning, it is common for each pixel in a sensor to receive a mixed spectrum due to the mineral size being finer than the sensor resolution. If certain conditions are met, the mineral mixing is considered linear, and linear unmixing can be used to measure the abundance of each mineral present. These conditions can be summed up by each photon only interacting with a single mineral, so that the signal received is a sum of photons from individual minerals. These minerals are the endmembers, and their known spectral signatures can be used as the characteristics for linear unmixing of the hyperspectral data to find the fractional abundances of the minerals (Bioucas-Dias et al. 2012; Dobigeon et al. 2009; van der Meer 1999). Linear unmixing can also be applied to hyperspectral data in many other diverse applications, for example, mapping coral bathymetry (Liu et al. 2018) or identifying sea ice type and concentration (Chase and Holyer 1990).

The chemical composition of a sample alone cannot provide all of the information that is desired for mining and processing. For example, factors such as hardness, crystallinity, and element substitution can affect the processing and upgradability of ore. While there are methods that can directly measure the minerals, such as X-ray diffraction (XRD), they are expensive and time-consuming. Therefore, they are typically not routinely performed during a mining operation. However, when the minerals present in a deposit are known, along with their typical chemical composition, linear unmixing can be used to calculate the mineral composition of a particular sample (Silversides and Melkumyan 2017; Tolosana-Delgado et al. 2011). In this situation, the characteristics are the measured chemical species, the endmembers are the pure minerals, and the samples are the geochemical assays of the mixed composition rocks. Examples of using linear unmixing to determine mineralogy include mineral

composition in production holes in banded iron formation (BIF) hosted iron ore (Silversides and Melkumyan 2017), determining sediment mixtures in moraines in retreating glaciers (Tolosana-Delgado et al. 2011) and determining the mineral composition of deep-sea manganese nodules (Renner et al. 2014). Note that this application uses compositional data. Further information on compositional data and methods of processing is presented in other chapters.

Summary

Linear unmixing involves calculating the composition of a mixed sample using the characteristics of the sample and the characteristics of the endmembers. If the characteristics of the endmembers are unknown, then bilinear unmixing is used to find these characteristics simultaneously with the proportions of the endmembers present in the mixture. Linear unmixing has a wide range of geoscientific applications including mineral identification from hyperspectral sensing and determining mineralogy from bulk chemistry.

Linearity

Christien Thiart

Department of Statistical Sciences, University of Cape Town, Cape Town, South Africa

Definition

Linearity possesses the properties of additivity and homogeneity and furthermore, from a statistical point of view, it means linear in the parameters/coefficients or weights. For clarity consider the following simple relationship between Y and X $Y = \beta_0 + \beta_1 f(X)$, where β_0 and β_1 are known as the parameters/coefficients and $f(X)$ is any function of X that does not depend on any of the parameters. If $f(X) = X$ then this relationship would be a straight line crossing the Y axis at β_0 and the slope of the line is determined by β_1 , e.g., one-unit change in X will cause a change of β_1 in Y .

Introduction

Linearity is everywhere: conversion from one scale to another; an assumption of linear models, linear regression, logistic regression, and even in interpolation methods for spatial data. To expand our simple definition, consider the following scenarios:

Conversion Formula

Linearity can be as simple as a formula for conversion from one scale to another, e.g., to convert temperature from degrees Celsius (C) to degrees Fahrenheit (F):

$$F = \frac{9}{5}C + 32$$

This can easily be visualized by an XY-plot, with the Celsius temperature on the X axis and the Fahrenheit temperature on the Y axis. A straight line will show the relationship between the different measurements of temperature. It would be an exact line, with the intercept of the Y axis (F) at 32, the

slope of the line $\frac{9}{5}$ and the correlation coefficient between Fahrenheit and Celsius equal to one.

Linear Regression

An approach to find the best linear relationship between a response (dependent variable) and a set of independent/explanatory variables is known as linear regression. Consider the following linear regression model:

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

where $\mathbf{Y}$ is a $n \times 1$ response vector, $\boldsymbol{\beta}$ is an $r \times 1$ vector of unknown coefficients, $\mathbf{X}$ is a $n \times r$ matrix of nonrandom explanatory variables whose rank is r ($n > r$), and $\boldsymbol{\varepsilon}$ is $n \times 1$ vector of random error, with $\boldsymbol{\varepsilon} \sim (\boldsymbol{\tau}, \boldsymbol{\Sigma}_\varepsilon)$, $E(\boldsymbol{\varepsilon}) = \boldsymbol{\tau}$ and $\text{Var}(\boldsymbol{\varepsilon}) = \boldsymbol{\Sigma}_\varepsilon$.

In the case of uncorrelated errors the expectation and variance of $\boldsymbol{\varepsilon}$ are $E(\boldsymbol{\varepsilon}) = \boldsymbol{\tau} = 0$ and $\text{Var}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$, where $\mathbf{I}$ is an identity matrix. Ordinary least square (OLS) produces best linear unbiased estimates (BLUE). Sometimes we also make the convenient assumption of normality, $\boldsymbol{\varepsilon} \sim N(\boldsymbol{\tau}, \sigma^2 \mathbf{I})$, allowing us to investigate various hypotheses for the $\boldsymbol{\beta}$'s and goodness-of-fit tests. Furthermore, under normality the conditional expectation of Y , given that $X = x$, is linear in x :

$$E(\mathbf{Y}|\mathbf{X}=x) = \mu_Y + \frac{\rho\sigma_Y}{\sigma_X}(x - \mu_X)$$

where the parameters μ_Y and μ_X are the population means of Y and X , ρ is the correlation coefficient between X and Y , and σ_Y and σ_X the standard deviations. The conditional expectation is also called the regression curve of Y on x . A special case is the simple linear model where, for example, we only have one X variable:

$$\mathbf{Y} = \beta_0 + \beta_1 \mathbf{X}$$

This equation is linear both in the parameters (the β 's) and in the variable X . If we consider a polynomial function of the X variables, say of order s

$$\mathbf{Y} = \beta_0 + \beta_1 \mathbf{X} + \beta_2 \mathbf{X}^2 + \dots + \beta_s \mathbf{X}^s$$

then this equation is linear in the parameters (the β 's) but not linear with respect to the variable X . Even if at first glance an equation/line does not look linear/straight, we can transform it to obtain linearity. Consider

$$\mathbf{Y} = e^{\beta_0 + \beta_1 \mathbf{X}}$$

then by taking the natural log on both sides we obtain

$$\log \mathbf{Y} = \beta_0 + \beta_1 \mathbf{X}$$

which is now linear. When presented with a nonlinear function, it is useful to transform the variables in order to obtain linearity. Transformations to achieve linearity are outside the scope of this article, and help is easily available in any multivariate regression book (e.g., Mosteller and Tukey 1977).

Visualizing Linearity

In the case of bivariate variables it is easy to visualize the association between them with a scatterplot (XY-plot). One variable (usually the independent variable) defines the X axis and the other (dependent) variable defines the Y axis. The points on this graph represent the relationship between the two points. If the points lie on a straight line (as in our temperature example), we have perfect correlation between X and Y . In this case the correlation coefficient $r_{XY} = 1$, indicating a perfect positive relationship.

The correlation coefficient lies between -1 and $+1$. If the correlation coefficient is near 0 , no linear relationship between the two variables exists. Values of the correlation coefficient near ± 1 are an indication of strong linear relationships. But be aware the correlation coefficient is not a “test” or an indication of linearity. It is good practice to always inspect the residuals after fitting a model. The residuals are defined as the difference between the observed value and the predicted value ($\hat{\mathbf{Y}}$)

$$\hat{\boldsymbol{\varepsilon}} = \mathbf{Y} - \hat{\mathbf{Y}} = \mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}$$

In the residual (some practitioners prefer the studentized residuals) by predicted scatterplot ($\hat{\mathbf{Y}}$), we see that the residuals are randomly scattered around zero, with no obvious nonrandom pattern, the so-called “null plot.” Nonlinearity, outliers, and influential observations will be easily identified for further investigation. Outliers are observations that are inconsistent with the rest of the observations, and influential points are single points far removed from the others. Both outliers and influential observation can affect the regression results (the regression coefficients $[\beta's]$ and the correlation coefficient).

Linear Dependence

Linearity can also be linked to the collinearity problem. Collinearity happens easily in observational studies, and the

$\mathbf{X}$ matrix representing the independent variables in the linear model can be rank-deficient. The rank of a matrix is defined as the number of linearly independent columns/rows in the matrix. No linear dependencies among the columns indicate that the matrix is of full rank or nonsingular. If the matrix is singular (some linear dependencies) we have collinearity. Collinearity leads to instability of the regression coefficients, sometimes resulting in nonsense coefficients and coefficients with very large standard deviations. The whole process is unstable and adding small random errors in $\mathbf{Y}$ causes large shifts in the coefficients. The regression results are unstable (Rawlings et al. 1998).

Linearity in Interpolation Methods for Spatial Data

Suppose that observations are made on an attribute Z at n spatial locations $\mathbf{s} = (\mathbf{s}_1, \dots, \mathbf{s}_n)$ in a designated geographic region D . Let $Z(\mathbf{s}_g)$ denote the observed response at a generic location $\mathbf{s}_g$, where $\mathbf{s}_g \in D \subset \mathbb{R}^d$, and let $\mathbf{Z}(\mathbf{s})$ denote the $n \times 1$ vector of responses at the n locations. The prediction $Z(\mathbf{s}_0)$ at location $\mathbf{s}_0$ in D is usually a (linear) weighted sum of the observations observed around it:

$$\hat{Z}(\mathbf{s}_0) = \sum_{i=1}^{N(\mathbf{s}_0)} \lambda_i \cdot Z(\mathbf{s}_i) = \boldsymbol{\lambda}^T \mathbf{Z}(\mathbf{s}),$$

where λ_i is the weight associated with the i th observation $Z(\mathbf{s}_i)$ with $\sum_{i=1}^{N(\mathbf{s}_0)} \lambda_i = 1$, $\boldsymbol{\lambda} = [\lambda_1, \dots, \lambda_{N(\mathbf{s}_0)}]$, and $N(\mathbf{s}_0)$ is the number of points in the search neighborhood around the prediction location $\mathbf{s}_0$.

For inverse distance interpolation the weights will be a function of the distance between points and for kriging the weights are obtained by minimizing the mean square prediction error.

Example

To illustrate the concept of linearity and the importance of visualization, we consider three small datasets. Dataset 1 is generated using a simple linear regression model: $Y = 5 + 5X + \varepsilon$, where $\varepsilon \sim N(0, 1.44)$ is a random error term, X is a sequence of numbers evenly spaced from 0 to 10 , and $n = 31$. Dataset 2 is generated by adding a quadratic term: $Y = 5 + 5X + X^2 + \varepsilon$ and dataset 3 is generated using an exponential model: $Y = 5 * \exp[-\frac{1}{2}X + \varepsilon]$.

Dataset 1: We fit a simple linear regression model to give $Y = 5.18 + 4.99X$, $R^2 = 0.99$ (blue line, Fig. 1, top left). For the fitted values versus residuals plot we observed a roughly

Linearity, Fig. 1 Analysis of simulated datasets. Row one is dataset 1, generated from a simple linear regression model; row two is dataset 2, generated from a quadratic model; and row three is dataset 3, generated from an exponential model. First column: scatter plot of observed points; blue line is the fitted simple linear regression model, red line is a fitted

model improving on the simple regression model (if applicable). The middle column presents fitted values versus residuals for the regression models and the last column the fitted values versus residuals for the improved model (if applicable)

centered random pattern around 0 with one possible outlier (Fig. 1, top middle). The residual plot and the $R^2 = 0.99$ are an indication of a good fit.

Dataset 2: We first fit a simple linear regression model to give $Y = -10.9 + 15X$, $R^2 = 0.97$ (blue line, Fig. 1, row 2 left). The corresponding fitted values versus residual plot for this model (Fig. 1, row 2 middle) shows a systematic pattern; the residuals are positive for small X values and large X values and negative for X values in between. When we add a quadratic term, the resulting fitted model $Y = 5 + 5.1X + X^2$, $R^2 = 0.99$ (red line, Fig. 1, row 2, left) produces a residual versus fitted plot that shows a centered random pattern around zero (Fig. 1, row 2 right). Note that the R^2 value of 97% for the simple regression model is very high and misleading, thereby illustrating the concept that one cannot just interpret the output of a model without inspecting the residuals.

Dataset 3: We first fit a simple linear regression model to give $Y = 6.4 - 0.8X$, $R^2 = 0.41$ (blue line, Fig. 1, bottom left). But if one looks at fitted values versus residuals (Fig. 1, bottom middle), we observe a nonrandom pattern. If we fit a model by taking the log of the Y 's (red line, Fig. 1, bottom left), then $Y = \exp(2.1 - 0.49X)$, $R^2 = 0.74$, and the resulting plot of fitted values versus residuals (Fig. 1, bottom right) is now a random pattern around zero.

Summary

Linearity is everywhere, either exactly or approximately; it can be a simple conversion formula but can also be an important assumption of various models, e.g., linear models, linear and logistic regressions. In the case of spatial data, predictions at unknown locations are linear weighted sums of the locations observed around the unknown locations. Visualization is a useful tool to judge the linearity between bivariate variables; if we have linear dependence between exploratory variables it can lead to collinearity, resulting in instability of the fitted model. Even when a function is nonlinear, for many purposes it can be useful as a start to approximate it by a linear function.

Local Singularity Analysis

Wenlei Wang¹, Shuyun Xie² and Zhijun Chen²

¹Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China

²China University of Geosciences (Wuhan), Wuhan, China

Definition

Local singularity analysis as a fractal-based concept was initially proposed to investigate anomalous distributions of ore elements (Cheng 1999). Formally defined in the *Dictionary of Mathematical Geosciences* (Howarth 2017), the concept of singularity analysis is “In geochemical applications, the singularity also can be directly estimated from the slope of a straight line fitted to a log transformed element concentration value as a function of a log transformed size measure. Areas with low singularities can be used to delineate anomalies characterized by relatively strong enrichment of the elements considered. Local singularity maps usually differ significantly from maps with geochemical anomalies delineated by other statistical methods.” In geologic applications, local singularity analysis is an effective method of quantitatively and qualitatively characterizing irregular energy release and/or material accumulation within relatively short spatial-temporal intervals generated by nonlinear geoprocesses (Cheng 2007). In a local comparison of element concentrations (or other physical quantities) between samples and their vicinities, spatially varied physicochemical signatures can be quantified using a singularity index (i.e., a measure of the intensity of variations or changes). As an example of the investigation of local signatures (e.g., ore element concentrations) across space, spatial variations of geoanomalies associated with mineralization can be evaluated. After more than 10 years of development, local singularity analysis has been extended to characterize many nonlinear geoprocesses and extreme geoevents as part of geological, geophysical, and litho-geochemical data analyses.

Introduction

In the context of earth science, geoanomalies having geologic signatures distinctive from those of their surroundings are a

major focus in the study of the nature of hazards, the environment, and energy and mineral resources for the survival and development of human society. Geoanomaly analysis has become a fundamental technical route in many subdisciplines of earth science. In past centuries, both linear and nonlinear methodologies have played important roles in the locating and characterizing of geoanomalies. Statistical methods including univariate and multivariate analyses (e.g., the use of a Q-Q plot or bi-plot cluster) are broadly adopted for their effectiveness in solving problems in the statistical frequency domain rather than the spatial domain. With the development of applications in geology, a branch of statistics termed geostatistics has been proposed to predict ore grades in the mining industry and is maturely applied in various branches of geology and geography. Most observational datasets in spatial and spatial-temporal forms can be effectively interpreted in the spatial domain. In the early stage of its application in geological exploration, geostatistics was based on the hypothesis that mineralization-related geovariates (i.e., geochemical data) follow a normal or log-normal distribution (Ahrens 1953). The simplest and classical method of identifying a geoanomaly from the background is the use of an algorithm based on the mean (μ) $\pm$ standard deviation(s) (e.g., σ , 2σ , or 3σ) (Fig. 1). Many mineral deposits have been discovered from geoanomalies identified by geostatistical methods, especially geochemical anomalies. Besides the adoption of the above type of algorithm, other approaches including the use of multielement indices, principal component analysis, independent component analysis, multidimensional scaling, and random forests have been adopted successfully in Australia, Canada, and many other countries (Grunsky and Caritat 2020). However, with the advance of mineral exploration around the world, most easily discoverable mineral resources buried at a shallow depth have been exploited. Exploration fields now tend to be in covered areas, the deep earth, and other untraditional spaces. Geoanomalies now tend to be weak and difficult to identify from observational datasets adopting traditional geostatistical methods (Fig. 1).

Fractal methods that consider both the frequency distribution and spatial self-similarity have become popular in recent decades. Against this background, local singularity analysis, a typical fractal method, has been proposed to identify weak anomalies that have not been discovered owing to the strong variance of the background and/or deep burial (Fig. 1). Local singularity analysis has been shown to be efficient in enhancing weak geoanomalies and effective in discovering causative bodies (e.g., ore bodies) of geoanomalies in covered areas and deeply buried spaces. As introduced by Cheng (2007), local variations of ore elements have been investigated by local singularity analysis and evaluated using a singularity index. Weak geochemical anomalies produced by deeply buried ore bodies have been appropriately enhanced. Meanwhile, strong anomalies identifiable using traditional methods are

Local Singularity Analysis, Fig. 1 Schematic diagrams of the traditional method (a) and local singularity analysis (b) for the identification of a geoanomaly in a mineral district (c). In comparison with the

identification of a geoanomaly using the traditional method (d), local singularity analysis (e) is more effective in characterizing a weak geoanomaly

preserved without the loss of indicative patterns (Fig. 1). Local singularity analysis has since flourished in mineral exploration and other subdisciplines of earth science. Its application has been extended to investigate geological and geophysical data. The concept of the fault singularity has been proposed and used to characterize the development of fault systems indicative of mineralization-favoring spaces produced by faulting activity (Wang et al. 2012). In application to gravity and magnetic data, geophysical anomalies associated with mineralization have been enhanced, demonstrating that local singularity analysis allows improved and simplified high-pass filtering with the advantage of scale independence (Wang et al. 2013a). Recently, local singularity analysis has been applied to investigate earthquakes, magmatic flare-ups, continental crust evolution, and other extreme geological events (Cheng 2016). The progressive development of the theory, application and algorithms of local singularity analysis has had profound implications for the simulation, prediction, and interpretation of nonlinear geoprocesses.

Singularity Index

As local singularity analysis was originally defined in the context of hydrothermal mineralization (Cheng 1999), the mass $\mu(V)$ and density $C(V)$ of ore materials each have a power-law relationship with V :

$$\mu(V) = c(V)^{\alpha/E}, \quad (1)$$

$$C(V) = c(V)^{\alpha/E-1}, \quad (2)$$

where the constant c determines the magnitude of functions; E is the Euclidian dimension; and α is termed the singularity index. The scaling exponent α is a kernel parameter of local singularity analysis that preserves the shape of functions and changing behaviors of the ore materials at different scales of spatial-temporal intervals. Different physicochemical behaviors can be characterized on the basis of changes in the singularity index α . For $\alpha = E$, the ore materials follow a monofractal distribution that indicates that the mass $\mu(V)$ and density $C(V)$ are independent of the volume V . For $\alpha > E$, there is a negative singularity that corresponds to the depletion of ore materials. This implies that ore materials follow a multifractal distribution. For $\alpha < E$, there is a positive singularity that indicates that ore materials follow a multifractal distribution, implying enrichment as introduced in the definition of local singularity analysis.

Methods of Estimating the Singularity Index

Methods of estimating the singularity index have progressively advanced over two decades. The first proposed estimation method is the square-window-based method (Cheng 2007). In its application to geochemical data in two dimensions, the general estimation steps (Fig. 2) of the method are: (1) centering on a location i of the study area and predefining a

Local Singularity Analysis,

Fig. 2 Schematic diagram of the square-window-based method of estimating the singularity index (after Wang et al. 2018)

set of square windows with size $A(\varepsilon_i \times \varepsilon_i)$ and density $C[A(\varepsilon_i)]$; (2) plotting $C[A(\varepsilon_i)]$ and $A(\varepsilon_i \times \varepsilon_i)$ on a log-log plot (Eq. 3); (3) adopting the least-squares method to estimate the slope (k) of the linear relation between $\log C[A(\varepsilon_i)]$ and $\log \varepsilon_i$; (4) calculating the singularity index $\alpha_i = k + E$ or $k + 2$; and (5) iterating these steps at each location to estimate the spatial distribution of the singularity index of the study area. Equation 3 is written as

$$\log C[A(\varepsilon_i)] = c + (\alpha - E) \log(\varepsilon_i). \quad (3)$$

Selected Case Studies

Furthermore, algorithms of local singularity analysis have been developed to characterize geoanomalies more precisely and appropriately. As an example, geochemical signatures inherited from multiple geoprocesses are often those of heterogeneity and anisotropy. In addition to identifying the locations of geoanomalies indicative of mineralization, the characterization of the anisotropic distributions of the related mineralization is necessary. The directional window-based method was first proposed by Li et al. (2005). In this method, a series of directional (rectangular) windows are predefined to obtain $C[A(\varepsilon_i)]$ and ε_i (Fig. 3a). Other steps of estimating the singularity index α are similar to those in the square-window-based method. The variation in window size only follows changes in ε_i , and the estimation thus becomes a one-dimensional problem and $\alpha = k - 1$. Adopting this method, the spatial variation of geochemical behaviors along the initial (i.e., northward) direction is consequently characterized. Moreover, other directional singularity indices, such as the eastward-trending window-based index (Wang et al. 2018), can be estimated.

Wang et al. (2013b) proposed a geologically constrained local singularity analysis that is termed the fault-trace-

oriented singularity mapping technique and quantitatively describes interrelations between fault structures and ore-bearing fluids. In contrast with former window-based methods, fault traces are first divided equally into segments (Fig. 3b). Centering on one segment, a series of rectangular windows along the direction vertical to the segment is defined. Then, in steps similar to those discussed above, the fault-oriented singularity index is estimated to describe interactions between fault activity and fluid flow. A new fault property (Fig. 3c) is obtained by assigning the index to the fault segment: $\alpha > 1$ indicates a negative fault, or a gradual depletion of metals approaching the fault space, whereas $\alpha < 1$ indicates a positive fault, or a continuous enrichment of metals approaching the fault space.

Wang et al. (2018) further developed the directional window method and proposed the concept of the anisotropic singularity. Following the directional window method, the anisotropic singularity estimation focuses more on the intensity of anisotropic variations between samples and their vicinities. Centering on one sample location, series of rectangular windows trending along all directions are predefined (Fig. 3d). Using the estimation method discussed above, the direction with the maximum slope, or $|\alpha - 1|_{\max}$, is determined and used to obtain the singularity index for the current location, such that the variation (accumulation or depletion) characterized by $|\alpha - 1|_{\max}$ is greatest along the selected direction (Fig. 3e). In addition, as shown in Fig. 3f, directional patterns of element accumulation (with arrows directed from low to high) and depletion (with arrows directed from high to low) depict the anisotropy of geochemical behaviors appropriately.

Cheng (2017) applied the local singularity analysis to global databases of igneous and detrital zircon U–Pb ages. Figure 4 shows the U–Pb ages on a histogram. The episodic growth of the continental crust and the development of

Local Singularity Analysis, Fig. 3 Schematic diagrams of directional window-based (a), fault-trace-oriented (b, c), and anisotropic singularity index estimation methods (d, e, f) (after Wang et al. 2018)

Local Singularity Analysis, Fig. 4 Schematic diagram of the method of estimating the singularity index for histogram data in one dimension (a) and practical application in analyzing the global zircon U–Pb age series (Cheng 2017)

supercontinents are characterized by the age peaks. In analyzing the one-dimensional data, the estimation method (Fig. 4) was modified to have the steps of (1) choosing one bin of the histogram as the initial one-dimensional window; (2) while centering on this bin, defining a series of one-dimensional windows with size ε_i ; (3) plotting average numbers of recorded ages of bins within each window $C[A(\varepsilon_i)]$ and ε_i on a log-log graph; and (4) estimating the slope k using the least-squares method and using k to calculate the

singularity index for the initial bin, $\alpha = k + 1$. The case study well extends the application fields of local singularity analysis to lithogeochemical data, focusing on the shapes of age peaks depicted by the singularity index regardless of the bin size of the histogram (i.e., scale independency) rather than the amplitudes and periodicity of age series. The singularity indices of global data show that all age peaks have an episodic pattern with a duration of 600–800 Myr (Fig. 4) (Cheng 2017).

Conclusions

After more than 20 years of development, local singularity analysis has become a broadly used geoanomaly identification method, especially in the exploration of weak geoanomalies obscured by covering materials, owing to its advantages in quantifying spatial-temporal variations of physicochemical signatures generated by nonlinear geoprocesses. Initially applied in geochemical data analysis, spatially varied ore element concentrations have been characterized using the singularity index to represent accumulation and depletion in the comparison of samples within local vicinities. In the context of two-dimensional data analysis, geological and geophysical data have been investigated to delineate mineralization and other geoanomalies related to nonlinear geoprocesses, quantitatively and qualitatively. Algorithms have been further developed to satisfy geological constraints and the anisotropic nature of geoprocesses. In recent practice, local singularity analysis was adopted to simulate and predict extreme geological events that extend the application fields in earth sciences. In more widespread and profound application, local singularity analysis is expected to be adopted for new situations of geological singular events.

Locally Weighted Scatterplot Smoother

Klaus Nordhausen and Sara Taskinen

Department of Mathematics and Statistics, University of Jyväskylä, Jyväskylä, Finland

Definition

The locally weighted scatterplot smoother (LOWESS) uses local regression models to obtain a smooth estimator for the conditional expected value of response variable. The locality is defined based on a nearest neighbour-type approach assigning weights to the observations based on their distances from the point of interest as well as on their outlyingness which are then used in an iterative weighted least squares approach.

Introduction

A common problem in statistics is to identify the relationship between two variables, *i.e.*, between an explaining variable x and a response variable y based on a sample $(x_i, y_i), i, \dots, n$. Traditionally, the conditional expectation of y given x is modelled as a function of x , and we assume that the data are generated by

$$y_i = g(x_i) + \epsilon_i,$$

where $g(\cdot)$ is a smooth function and ϵ_i is some random fluctuation with $E(\epsilon_i) = 0$ and $Var(\epsilon_i) = \sigma^2$. When visualizing a scatterplot of x_i against y_i , one thus wants to see a smooth relationship in the conditional mean of y as a function of x .

Assuming $g(x) = \beta_0 + \beta_1 x$, where β_0 and β_1 are constants, a straight line is used to model the conditional mean of y , which is known as linear regression. However, in many practical problems, it seems an oversimplification to approximate $g(\cdot)$ with a linear function. The use of a polynomial of order d , *i.e.*,

$g(x) = \beta_0 + \beta_1 x + \dots + \beta_d x^d$, may also not be reasonable and may overfit the data and cause problems at the boundaries of x .

In many cases, it may be reasonable to assume that locally, in a neighbourhood of a point x , a linear regression provides a good approximation for the conditional mean of y . For such a local regression, observations close to x are naturally more relevant than observations further away, thus leading to the following weighted regression problem

$$\operatorname{argmin}_{\beta_0, \beta_1} \sum_{i=1}^n K\left(\frac{x_i - x}{h}\right) (y_i - \beta_0 - \beta_1 x_i)^2, \quad (1)$$

where K is a non-negative weight function called kernel, and the parameter h which defines locality is called the bandwidth. The bandwidth can be chosen, for example, using cross validation. This modelling approach is also known as local linear regression and is easily extended to the case of several predictors and to local polynomial regression.

Local linear regression has a long tradition and is discussed in detail in Loader (1999), for example. The main advantages of local linear regression are, according to Cleveland & Loader (1996), that (i) it is easy to understand and interpret, (ii) it adapts well to problems at the boundaries and regions of high curvature, and (iii) it does not require smoothness or regularity conditions. Many computational tools for local linear regression exist. In R, the method is available, for example, in the package *locfit* (Loader 2020).

Despite its flexibility, local linear regression as defined in (1) has some shortcomings. One disadvantage is that the method uses the quadratic loss function, which is well known to be sensitive to outliers. It is therefore natural to replace the quadratic loss function with a robust loss function and fit locally some robust regression model instead of a least squares regression. Local robust polynomial regression of order d can then be defined as

$$\operatorname{argmin}_{\beta_0, \beta_1, \dots, \beta_d} \sum_{i=1}^n K\left(\frac{x_i - x}{h}\right) \rho(y_i - \beta_0 - \beta_1 x_i - \dots - \beta_d x_i^d), \quad (2)$$

where ρ is a loss function. The data analyst must now choose the kernel function K , the loss function ρ , the order of the polynomial d , and the bandwidth h .

Locally Weighted Scatterplot Smoother

In this context, Cleveland (1979) suggested the locally weighted scatterplot smoother (LOWESS) which uses as a kernel the tricube weight function

$$K(x) = \left(1 - |d|^3\right)^3,$$

when $|d| < 1$, and 0 otherwise, where d is the distance from the neighbourhood sample points to the value x . Cleveland (1979) argues that such kernel is beneficial as it assigns points far away a zero weight and is therefore better than kernels based on symmetric densities which give usually all points some positive weight. Depending on the scale of x , it may then however be advisable to scale the observations. For the neighbourhood structure, LOWESS suggests an adaptive nearest neighbour method. Let $0 < f \leq 1$ be a tuning parameter and denote then $r = \lceil fn \rceil$ as the number of local data points to be used. At point x , those r points, for which $|x - x_i|$ is the smallest, then form the neighbourhood. As the next step, initial fits $\hat{y}_i$ at each data point are obtained using the local polynomial least square regression in order to obtain the residuals $r_i = y_i - \hat{y}_i$. These residuals are then robustly scaled using six times the median absolute deviation (mad), i.e., the median of $\{|r_1|, \dots, |r_n|\}$. To downweight large residuals, biweight kernel $B(t) = (1 - t^2)^2 I_{[-1,1]}(t)$ is then used to assign robust weights $\delta_i = B(r_i / (6 \text{ mad}))$. Based on this initial step, the procedure is then iterated M times so that the kernel $K(x)$ is multiplied with robust weights δ_i . Thus, this corresponds to local iterative weighted least squares (IWLS) where the weights depend on the distance from the point of interest and whether the point is considered as outlying.

The parameter values for LOWESS that need to be chosen are f , d , and M . Cleveland (1979) suggested to choose d from 0, 1, and 2 with a tendency to $d = 1$ as higher order polynomials tend to overfit the data and the method becomes numerically unstable. It is also argued that the number of iterations can be small, say $M = 2$ or $M = 3$, and no convergence criterion is needed. Parameter f has most impact on the results, as, when the value is increased, the smoothness of the fit increases. Thus, it is a trade-off between variability and recognizing the pattern. Cleveland (1979) suggests to start with $f = 0.5$ and limit the value to the range of $[0.2, 0.8]$. For automatic procedures, Cleveland (1979) suggests to first choose the initial f which minimizes $\sum_{i=1}^n (y_i - \hat{y}_{i,f})^2$ and then to choose the final f as the minimizer of $\sum_{i=1}^n \delta_i (y_i - \hat{y}_{i,f})^2$. Based on the final robust weights, one can then compute the fitted values $\hat{y}_1^*, \dots, \hat{y}_m^*$ for a grid of, not necessarily observed values, $x_1^*, \dots, x_m^*$ covering the range of the observed x 's. Using linear interpolation, these points can then be used to visualize the smooth function. For the theoretical properties of LOWESS under the assumption of iid errors following a Gaussian distribution, we refer to Cleveland (1979). The procedure in an algorithmic form is summarized in Algorithm 1.

Algorithm 1: LOWESS algorithm

Input: n data points (y_i, x_i) , $i = 1, \dots, n$;
 1 Set $f \in (0, 1]$ to specify the neighborhood;
 2 Set integer $d \geq 0$ as the degree of the local polynomial;

- 3 Set integer $M \geq 1$ for the number of iterations;
- 4 Compute the size of the nearest neighbourhood $r = \lceil fn \rceil$;
- 5 **for** $i \leftarrow 1$ **to** n **do**
- 6 For x_i , identify the r points forming the neighbourhood and denote them $x_{r_l}^i$, where $r_l \in \{1, \dots, i-1, i+1, \dots, n\}$ and $l = 1, \dots, r$;
- 7 Use these r points to fit a local polynomial regression model of order d using the kernel $K(x_{r_l}^i) = \left(1 - |x_{r_l}^i - x_i|\right)^3$;
- 8 Obtain the initial fit $\hat{y}_i$;
- 9 **for** $iter \leftarrow 1$ **to** M **do**
- 10 Calculate the residuals $r_i = y_i - \hat{y}_i$ and the median of absolute deviations (mad) of the residuals;
- 11 Compute the robust weights $\delta_i = B(r_i/(6 \text{ mad}))$;
- 12 **for** $j \leftarrow 1$ **to** n **do**
- 13 Use the neighbourhood points of x_j , $x_{r_l}^j$ and their corresponding robust weights $\delta_{r_l}^j$ to fit a local polynomial regression model of order d using the kernel $K(x_{r_l}^j) = \delta_{r_l}^j \left(1 - |x_{r_l}^j - x_j|\right)^3$;
- 14 Obtain the robust fit $\hat{y}_j$;
- 15 Predict y for any point of interest x ;

In R, LOWESS with $d = 1$ can be applied using, for example, the function `lowess`.

Extensions of LOWESS

Cleveland (1979) pointed out that LOWESS can be used with any kernel function, and also variants exist to speed up the computations for large data sets and for accommodating prior weights for the observations.

The main extension of LOWESS is however suggested in Cleveland & Devlin (1988) as locally estimated scatterplot smoothing (LOESS). LOESS generalizes LOWESS to the case of several predictors by replacing the simple regression with a multiple regression. Implementations such as LOESS in R let the user choose the degree of the polynomial d as well as the need for robust updates.

Example

To demonstrate LOWESS, we consider average yearly temperatures (in centigrades) of the German state Baden-Wuerttemberg from 1880 to 2020. The data can be obtained from the CDC-portal of the Deutscher Wetterdienst. Figure 1 shows the data together with three global polynomial least squares fits. All fits indicate an increase in average temperature but seem not to fit the data very well for early temperature records. We then apply LOWESS via the R function `loess` and visualize the results in Fig. 2 for different degrees of the polynomial (d) and different parameters defining the

Locally Weighted Scatterplot Smoother, Fig. 1 Yearly average temperatures ($^{\circ}\text{C}$) for Baden-Wuerttemberg in Germany together with three global fits

Locally Weighted Scatterplot

Smoother, Fig. 2 Yearly average temperatures ($^{\circ}\text{C}$) for Baden-Wuerttemberg in Germany together with locally smoothed fits

neighbourhood (f). Both, the robust variant with the IWLS steps as well as the pure local LS fits, are illustrated. The figure clearly shows that the differences between robust fits and LS fits are quite small indicating the lack of outlying observations. A quadratic polynomial seems however preferable, especially with a large value of f , and the LOWESS fit shows that after a long period of slow rise in average temperature, the rise has accelerated in the last 50 years. A more thorough analysis of temperature data using LOWESS is available in Wanishsakpong & Notodiputro (2018), for example.

Summary

LOWESS and its extension LOESS are powerful and simple regression methods ideal for situations where an initial model assumption is not available, as the methods do not use any special model specification. LOWESS exploits locality which means that it requires dense observations to fully achieve its strengths. While LOWESS was originally designed for models with signal predictors, LOESS allows more predictors meaning that the method creates smooth surfaces which then need even denser data and a careful choice for the notion of distance.

Logistic Attractors

Balakrishnan Ashok
Centre for Complex Systems and Soft Matter Physics,
International Institute of Information Technology Bangalore,
Electronics City, Bangalore, Karnataka, India

Definition

The logistic map is a common starting point for modeling growth phenomena in various fields due to not only its simple

form but due to the extensive and rich dynamics it displays. Systems in nature typically display nonlinear behavior, and the logistic map is a quadratic nonlinear equation that can be extensively analyzed, even as it shows both regular and chaotic behavior, depending upon the value of the control parameter. A logistic attractor, as the name implies, is an attractor associated with the logistic map and can correspond to either a fixed point or a limit cycle or even chaotic oscillations.

Logistic Map and Logistic Function

To understand how logistic attractors appear in nature, an overview of the associated logistic map or difference equation is required, as also the associated logistic differential equation and logistic function, which are discussed briefly in this section. The logistic map is the quadratic map defined as

$$x_{n+1} = rx_n(1 - x_n), \quad (1)$$

with $0 \leq x_n \leq 1$, $0 \leq r \leq 4$.

This was first discussed at length by May (1976) in the context of modeling population growth from one generation x_n , to the next, x_{n+1} , with a growth rate r serving as the control parameter. The logistic map is the discrete analog to the logistic differential equation

$$\frac{d}{dt}x(t) = rx(t)(1 - x(t)), \quad (2)$$

which has the logistic function

$$x(t) = m/(1 + \exp(-r(t - t_0))) \quad (3)$$

as its solution, with r being termed the logistic growth rate, and m being the maximum value of $x(t)$. Figure 1 shows examples of logistic functions with various values of growth rate and maximum value. The logistic differential equation was introduced by Pierre Francois Verhulst as an improvement over the Malthusian exponential growth model for population growth (Verhulst 1838). The assumptions made in formulating the logistic function are that the population in each new generation is proportional to the then-current one for smaller populations, and there is a maximum population level, M , reaching that results in population extinction in the subsequent generation. This gives

$$N_{n+1} = rN_n(1 - N_n/M), \quad (4)$$

If the population N_n in generation n is taken to represent the fraction of the maximum value M , and normalizing M so that $M = 1$ and $0 \leq N_n \leq 1$, with r as the growth rate, this has the same form as Eq. (1), which is also known as the logistic difference equation or the discrete logistic equation.

Logistic Attractors, Fig. 1 Plot of the logistic function $f(x)$ versus x for different values of the growth rate r and maximum value m and midpoint $x_0 = 0.6$: curve (1) $m = 1.0$, $r = 0.5$; curve (2) $m = 1.5$, $r = 0.5$; curve (3) $m = 1.0$, $r = 1.5$

Stability and Attractors

The logistic map has several attractors, which vary depending upon the value of the control parameter. These can be fixed points, limit cycles, or chaotic attractors. Fixed points, x^* , for the logistic map exist when

$$f(x^*) \equiv x^* = rx^*(1 - x^*), \quad (5)$$

which would imply that $x^* = 0$ or $x^* = 1 - 1/r$. Regardless of the value of the control parameter, the logistic map always has a fixed point at the origin $x^* = 0$. $x^* = 1 - 1/r$ is a fixed point for $r \geq 1$. The stability of these fixed points can be obtained from $f'(x^*) = r - 2rx^*$, with stable fixed points resulting from $|f'(x^*)| < 1$ and unstable fixed points from $|f'(x^*)| > 1$. At $x^* = 0$, $f'(0) = r$, which would be stable for $r < 1$ and unstable for $r > 1$.

At the fixed point $x^* = 1 - 1/r$, $f'(x^*) = 2 - r$, stable fixed points would require $1 < r < 3$, and $r > 3$, resulting in all extant fixed points being unstable. Evolution of the stability of the system as a function of the control parameter can be observed from a return map of x_{n+1} versus x_n , as shown in Fig. 2. The intersection of the diagonal with the parabola would be at the fixed point since $x_{n+1} = x_n$ there. Three typical curves are shown for values of r less than, equal to, and greater than 1. As can be seen, for $r < 1$, the origin can be

the only fixed point since the parabola falls below the diagonal. It will be noted that increasing r makes the parabola steeper so that the diagonal is tangent to it when $r = 1$. For $r > 1$, the second fixed point is located at the intersection of the diagonal with the parabola, with the other fixed point continuing to be the origin, which, however, loses stability. Hence, at $r = 1$, x^* bifurcating from the origin occurs through a transcritical bifurcation.

For $1 < r < 3$, the logistic map has an attractor at $x^* = 1 - 1/r$, which is a fixed point for the system. The system shows its first bifurcation to a period-2 cycle at $r = r_1 = 3$, where a flip bifurcation or period-doubling bifurcation occurs. This attractor exists for $3 \leq r \leq 3.449$, after which a second period-doubling bifurcation occurs at $r = r_2 = 3.449$ with the appearance of another attractor, a period-4 cycle, followed by further period-doubling attractors at $r_3 = 3.54409$, $r_4 = 3.5644$, and so on till $r = r_\infty = 3.569946$, at which point chaotic behavior sets in. The presence of these attractors can also be easily seen from the orbit diagram for the logistic map, shown in Fig. 3. As can be seen, the first period-doubling bifurcation occurs at $r = 3$, followed thereafter by further period-doubling bifurcations as mentioned above.

After the onset of chaotic behavior, there are again windows of periodic behavior, including the period-3 window that appears at $r \approx 3.83$. The appearance of a period-3 cycle in a system is an indicator of the presence of chaotic behavior –

Logistic Attractors, Fig. 2 Plot of x_{n+1} versus x_n for the logistic map, showing the location of the fixed points for three different r values

Logistic Attractors, Fig. 3 Orbit diagram for the logistic map showing period-doubling. Sections of panel (A) are shown magnified in (B–F). A period-3 cycle can be seen in panel F after $r \approx 3.83$

“period 3 implies chaos” as was proved by Li and Yorke in their famous paper with the same title (Li and Yorke 1975). Self-similarity can also be seen in the orbit diagram of the logistic map, with the branches seeming to repeat endlessly at finer and finer scales, as can be seen in Fig. 3. The appearance of n -cycles and attractors can also be observed by constructing a cobweb diagram for the map, which is a graphic method of locating fixed points and cycles. Cobweb diagrams illustrating the stability of the attractors of the logistic map are shown in Fig. 4 for six distinct r values, $r = 1.5, 2.0, 2.8, 3.2, 3.5$, and 3.9 . For $r = 1.5$ and $r = 2.0$, and $r = 2.8$, the fixed point at the origin $x^* = 0.0$ is a repelling one while the fixed point at $x^* = 1 - 1/r$ is attracting. That is, $x^* = 0.33, 0.5$, and 0.64 are attracting for $r = 1.5, 2$, and 2.8 , respectively. At $r = 3.2$, both the fixed points (at $x^* = 0$ and $x^* = 0.6875$) are repelling fixed points, as seen in part (d). The attractor at $r = 3.5$ (e) is a period-4 cycle while for $r = 3.9$ shown in (e), a multitude of cycles are possible, and a chaotic attractor is evident. The behavior of the logistic equation and the logistic map is extensively discussed in the dynamical systems theory literature, including, for example, in Strogatz (1994). In the context of geophysical applications, one can also refer to the work of Turcotte (Turcotte 1997) for an introduction to the logistic map and dynamical systems.

In Geophysics

The logistic equation can be extended to more generalized forms, such as

$$\frac{d}{dt}x(t) = px(t)^q(1 - (x(t)/k)^c)t^n, \quad (6)$$

with p, q, k, c, n being constants, allowing for the modeling of various systems showing still further rich dynamics. In a recent work (Maslov and Anokhin 2012), Maslov and Anokhin used such a generalized logistic equation to derive the empirical Gutenberg–Richter equation relating the magnitude m of an earthquake to its frequency f (Gutenberg and Richter 1942), similar to that obtained by Ishimoto and Iida, earlier (Ishimoto and Iida 1939). The Gutenberg–Richter equation

$$\log(F) = a - bm \quad (7)$$

depicts the logarithmic relation between earthquake frequency and magnitude, a and b being constants. Considering one special case of the Eq. (6):

Logistic Attractors, Fig. 4 Cobweb diagram for the logistic map for $r =$ (a) 1.5, (b) 2.0, (c) 2.8, (d) 3.2, (e) 3.5, and (f) 3.9

$$\frac{d}{dt}x(t) = rx(t)(M - x(t))t^\alpha, \quad (8)$$

Maslov and Anokhin show that a generalized Gutenberg–Richter formula

$$\ln F(m) \approx \ln A - \frac{s}{\alpha + 1} m^{\alpha+1} \quad (9)$$

can be obtained by appropriate identification and redefinition of variables with those in the generalized logistic equation. The usual Gutenberg–Richter formula can be obtained by taking $\alpha = 0$, $a = \ln A$ and $b = s$.

A generalized logistic equation can also be used to model natural phenomena, including earthquakes and landslides, and the kinetics of such events that involve hierarchical aggregation, as has been proposed by Maslov and Chebotarev (Maslov and Chebotarev 2017), where the function $x(t)$ in Eq. (6) is replaced by $N(A)$, with A corresponding to the basic size of an element in a structure, and may correspond to, in the context of the problem being modeled, the magnitude of an earthquake or even area or mass. The function N is interpreted as a measure of the number of elements that are of size smaller than A . Equation 6 then serves to model the rate of growth of a particular phenomenon. The distributions of fore- and aftershocks of the 2014 Napa Valley earthquake, as well as the 2004 Sumatra earthquake, were modeled using the solution of the generalized logistic equation in Maslov and Chebotarev (2017) and showed good agreement, both qualitatively and quantitatively, with observed data points. Other researchers have also used generalized logistic functions to model fracture propagation and growth and include self-similarity in the fracture process (Lyakhovsky 2001).

Summary

Logistic attractors are the fixed points or limit cycles of the logistic difference equation. Despite the very simple form of this unimodal map, its nonlinear behavior gives rise to both simply periodic behavior, as well as period-doubling behavior with the number of stable solutions doubling, eventually showing chaotic behavior, after appropriately changing the value of the control parameter. The logistic map or its counterpart in continuous systems, the logistic equation, can be used to model varied growth phenomena and is useful in modeling geological phenomena such as earthquakes, fluid flows, as well as fracture propagation.

Logistic Regression

D. Arun Kumar

Department of Electronics and Communication Engineering and Center for Research and Innovation, KSRM College of Engineering, Kadapa, Andhra Pradesh, India

Definition

Logistic regression (LR) generates the probability of outcome for the given input variable. The most commonly used LR is with binary outcome such as 1 or 0, true or false, and yes or no. In multinomial LR model the number of discrete outcomes are more than two. Logistic regression is used to predict the class label of an unknown sample/pattern to a category. LR is used in the data classification applications.

Introduction

Advancement in the sensor technology produced a large amount of spatial data. The spatial data is processed to obtain the information related to the ground area of interest (Bishop 1995). There are various methods of spatial data analysis techniques to extract the information from the data of

different dimensions. The spatial data analysis techniques are broadly classified as data classification, data regression, and data clustering. Data classification is assigning class label to the data sample (Duda et al. 2000). Data clustering is grouping the data samples in to individual groups without class labels. Data regression analysis is predicting the numeric values of output variable for the given input variables. The classification methods like Logistic regression, K-nearest neighbor classifier, minimum distance to mean classifier, etc., are used for spatial data analysis. The regression methods like linear regression, robust regression, probit regression, ridge regression, etc., are used to compute the values of output variable. The methods like K-means clustering, density-based clustering, and hierarchal clustering are used to group the data samples without class labels.

There exist various types of regression models to predict the unknown values of output variable. The models such as linear regression and logistic regression are frequently used to predict the values of a output variable. The linear regression model is used to predict continuous values of output variable such as predicting the slope value of a terrain from digital elevation model (DEM) image. The predicted continuous values of output variable are not sufficient to identify the number of classes present in the dataset. With this motivation logistic regression is suggested for data classification.

LR was first introduced in nineteenth century to predict the population growth (Bacaër 2011). The LR model was later updated in order to expand the model to classify the population of various countries (Wilson and Lorenz 2015). LR model is used to predict the discrete values of output variable. The discrete values are also called as class labels. The logistic regression model is mathematically represented in the form of nonlinear equation with activation function to provide the discrete values. There are various types of logistic regression models for data classification such as binary logistic regression, multinomial logistic regression, ordinal logistic regression model, etc. In the present study, a binary logistic regression model is explained with an example.

Logistic Regression Analysis

With traditional linear regression model, the output variable is generated as continuous values (Duda et al. 2000). The continuous values produced by linear regression have the limitation in producing class discrimination among the samples in the dataset. This limitation of regression model is solved by producing the probability of input sample/pattern to a given class. The functional block diagram of logistic regression model is provided in Fig. 1. The data samples are collected to prepare the dataset and furthermore, a logistic regression model is trained with the training samples. Let a sample/Pattern (P) in the dataset is associated with n number of

Logistic Regression, Fig. 1 Logistic Regression model for data analysis. The model considers input data, preprocessing of input data, training the logistic regression model, classifying the data, and assigning the class label to the data

feature values. The patterns are represented as points in n -dimensional feature space with each axis named as feature axis. The linear regression model for the training dataset is mathematically given in Eq. 1.

$$z = a_0 + a_1x_1 + a_2x_2 + \dots + a_nx_n, \quad (1)$$

where $a_0, a_1, \dots, a_n$ are coefficients or weight parameters, $x_1, x_2, \dots, x_n$ are feature values for n features in a sample. During the training stage, the coefficients $a_0, a_1, \dots, a_n$ are updated by passing each input sample/pattern based on back propagating the output error (Theodoridis and Koutroumbas 1999). Linear regression model predicts continuous numeric values to the output variable data analysis (Cramer 2002). The model considers input data, preprocessing of input data, training the logistic regression model, classifying the data, assigning the class label to the input sample.

The limitation of linear regression is to predict discrete output value and represent the corresponding class label (Lever et al. 2016). The logistic regression model uses sigmoid activation function to generate the probabilities of input samples to the respective classes in the dataset. The sigmoid function generates output value in the range (0,1) for all the input real numbers (Hilbe 2009). Hence, if the input to the function is either a very large negative number or a very large positive number, the output is always between 0 and 1.

The predicted probabilities are used by the model to label sample to the respective class. The output of logistic regression model is computed as according to Eq. 1.

$$y = \frac{1}{(1 + e^{-z})} \quad (2)$$

The output value z is passed through sigmoid activation function and final output is obtained according to Eq. 2. The value of y is estimated in range [0,1] (according to Eq. 2) and the value indicate the probability of input sample belonging to a class (Ji and Telgarsky 2018). The plot for sigmoid activation function is given in Fig. 2.

Logistic Regression, Fig. 2 Pictorial representation of sigmoid activation function. The x-axis represents input variable (z) and y-axis represents output variable (y)

During the training phase, each sample/pattern is passed as an input and the corresponding output is computed. The output value of logistic regression model is compared with the target value and the output error is computed to update the coefficients. Updating the coefficients of logistic regression model is also termed as learning process. The learning process is implemented by decreasing the cost function near to zero by training the logistic regression model to multiple number of iterations. The cost of logistic regression model is given as,

$$E_r = \frac{1}{2} \sum_{i=1}^c y_i - d_i \quad (3)$$

where i is the number of output variables, y_i is the computed output value for i th class and d_i is desired value for i th class. Pictorial representation of cost function for multiple number of iterations is given in Fig. 3.

Furthermore, the logistic regression model is tested with test data, and corresponding class label is assigned to the test pattern by applying max operator. The labeled patterns are evaluated based on various evaluation metrics. The detailed list of evaluation metrics is given in the following section.

Evaluation of Logistic Regression Model

The classified samples using logistic regression model in output image are evaluated using different performance metrics such as overall accuracy (OA), precision (P), recall (R), kappa coefficient (KC), and dispersion score (DS). These performance metrics are derived from confusion matrix (CM). CM is a table of actual class labels assigned by logistic regression model to the patterns of different classes. OA is defined as the sum of diagonal elements of CM divide by total number of samples. Precision is ratio of relevant classified samples to the

Logistic Regression, Fig. 3 Cost value of logistic regression reduced from maximum value down to zero over 50 number of iterations

retrieved classified samples. Recall (R) is the ratio of retrieved classified samples to relevant classified samples. Kappa coefficient (KC) is the measure of overall performance of the model based on the individual classwise agreement. Dispersion score (DS) measures the distribution of classified samples among the classes present in dataset and also, specify the overlapping characteristics of various class boundaries. A classifier with less DS to a particular class has a better ability to classify the samples to the corresponding class.

Example – Logistic Regression

In the present study, Sentinel Multispectral Imager (MSI) dataset with two Land use/Land cover classes like Forest and Water are considered to fit the logistic regression model. The dataset consists of 600 pixel vectors such as 300 pixel vectors for each class. Each pixel in MSI Sentinel image is characterized by 12 features (12 spectral bands such as Band 1, Band 2, Band 3, Band 4, ..., Band 12). The pixel is represented as a point in 12D feature space. The dataset is divided in to training and testing sets with 60% of the pixels selected in to training set and remaining 40% pixels are used for test set. The logistic regression model is trained with train dataset and tested with test dataset. The application of logistic regression model on training dataset is given in Fig. 4. In Fig. 4, B1 and B2 are feature axis and 1, 2 are land use/land cover classes where class 1 is Forest and class 2 is Water. In Fig. 4, few samples of class 1 are assigned to class 2 and few samples of class 2 are assigned to class 1. The logistic regression model is tested with test dataset and the classified pixels in B1-B2 feature space is given in Fig. 5. In Fig. 5, the model classified the test samples with 98% OA. The performance of logistic regression model is similar to OA as tested with other metrics. A few test samples of test data are misclassified to other classes as shown in Fig. 5.

Logistic regression performs better in discriminating the samples of various classes in comparison with similar type of models such as supervised kernel based support vector machines (SVM) and ensemble methods. The LR model has the limitation of handling the data with complex relationship between independent variable and dependent variable. The performance of LR is less when the decision boundary among

Logistic Regression, Fig. 4 Logistic regression model applied on training set. X-axis represents the feature axis (Band – B1) and Y-axis represents the feature axis (Band – B2). The training data consists of class 1 – Forest (1) and class 2 – Water (2)

Logistic Regression, Fig. 5 Logistic regression model applied on test set. X-axis represents the feature axis (Band – B1) and Y-axis represents the feature axis (Band – B2). The test data consists of class 1 – Forest (1) and class 2 – Water (2)

the classes in the dataset is nonlinear. Furthermore, the combination of LR and dimensionality reduction technique would reduce the complexity between the independent variable and dependent variable and in turn would produce better classification results.

Conclusion

In the present study, logistic regression model for data classification is discussed. Linear regression model is used to predict the continuous values for output variable. The limitation of linear regression model is its inability to produce discrete classes to the pixels. Logistic regression model produces discrete classes to the pixels unlike continuous values produced by linear regression model. The advantage of

logistic regression model is due to the usage of sigmoid activation function. In the present study, logistic regression model is trained and tested with Sentinel MSI dataset. The logistic regression model produced 98% overall accuracy as tested with Sentinel MSI dataset. The logistic regression model can also be extended to multiclass data classification problems in higher dimensional feature space.

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence

Helmut Schaeben

Technische Universität Bergakademie Freiberg, Freiberg, Germany

Definition

Logistic regression is a generalization of linear regression in case the target variable is binary or categorical. Then the error

term is not normally distributed, and a least squares approach does not apply. The coefficients are estimated in terms of maximum likelihood leading to a system of nonlinear equations. A major application of logistic regression is the estimation of conditional probabilities updating prior unconditional probabilities. Assuming binary predictor variables that are jointly conditionally independent given the target variable the logistic regression model largely simplifies such that its coefficients get independent of one another and can be estimated by mere counting. They are recognized as Turing's Bayes factors in favor of $T = 1$ as against $T = 0$ provided by $B = 1$ (Good 2011), the Bayes log-factors, or eventually the weights of evidence (Good 1950, 1968). Mineral prospectivity modeling, where the data and the probabilities refer to given locations, applies among other methods logistic regression and weights of evidence even though they cannot account for spatially induced dependencies in the data and the probabilities to be estimated.

Introduction

The very definition of probability and its estimation have kept mankind, dilettantes, and professionals busy for centuries. Logistic regression and weights of evidence are two methods to estimate the conditional probability of an event given additional information conditioning the targeted event. The practical application of the latter is hampered by the requirement that the random variables representing the conditions are jointly conditionally independent given the random variable representing the target event. In prospectivity and exploration, geosciences are expected to predict the probability of a specified mineralization at a given location if conditions in favor or to its disadvantage are provided at this location. Neglecting the spatial reference of both the target and the predictor variables, logistic regression and, if joint conditional independence holds, weights of evidence apply. Weights of evidence has been geologists' most favorite method because of its apparent simplicity. However, the simplicity is deceiving as the modeling assumption of joint conditional independence is involved. The choice of the predictor variables to be sampled is usually guided by geological knowledge of the processes triggering a specified mineralization. Thus a flavor of causality modeling is added to the obvious regression problem to estimate a probability. In fact, conditional independence is a probabilistic approach to causality.

Mathematical Basics

Stochastic Independence

Let $(\Omega, \mathcal{A}, P)$ be a probability space. The events $B_1, \dots, B_m \in \mathcal{A}$ are jointly independent, if

$$P\left(\bigcap_{\ell=1}^k B_{i_\ell}\right) = \prod_{\ell=1}^k P(B_{i_\ell}) \quad (1)$$

for each k -tupel $(i_1, \dots, i_k)$ with $1 \leq i_1 < \dots < i_k \leq m$, $k = 2, \dots, m$. The random variables $B_1, \dots, B_m$ defined on Ω mapping into the sets S_ℓ of the measurable spaces $(S_\ell, \mathcal{S}_\ell)$, $\ell = 1, \dots, m$, are jointly independent, if the events $B_\ell = B_\ell^{-1}(E_\ell)$ for any $E_\ell \in \mathcal{S}_\ell$, $\ell = 1, \dots, m$, are jointly independent. If the random variables possess the probability measures P_{B_ℓ} with $P_{B_\ell}(E_\ell) = P(B_\ell^{-1}(E_\ell))$, $\ell = 1, \dots, m$, then their joint independence is equivalent to

$$P_{B_1, \dots, B_m} = P_{\otimes_{\ell=1}^m B_\ell} = \bigotimes_{\ell=1}^m P_{B_\ell}, \quad (2)$$

that is, their joint probability is equal to the product of their individual probabilities.

Stochastic Conditional Independence

The random events $B_1, \dots, B_m \in \mathcal{A}$ are jointly conditionally independent of the event $A \in \mathcal{A}$ with $P(A) \neq 0$, if

$$P\left(\bigcap_{\ell=1}^m B_\ell | A\right) = \prod_{\ell=1}^m P(B_\ell | A), \quad (3)$$

that is, if the joint conditional probability of $B_1, \dots, B_m$ given A agrees with the product of the individual conditional probabilities of B_ℓ , $\ell = 1, \dots, m$, given A . Eq. (3) is equivalent to

$$P\left(B_k | \bigcap_{\ell=1, \ell \neq k}^m B_\ell \cap A\right) = P(B_k | A). \quad (4)$$

The random variables $B_1, \dots, B_m$ are jointly conditionally independent of the random variable T defined on Ω , if

$$P_{B_1, \dots, B_m | T} = P_{\otimes_{\ell=1}^m B_\ell | T} = \bigotimes_{\ell=1}^m P_{B_\ell | T}, \quad (5)$$

that is, if their joint conditional probability given T agrees with the product of their individual conditional probabilities given T .

- Independence does not imply conditional independence and vice versa.
- Conditionally independent random variables may be (significantly) correlated or not.
- Conditionally independent random variables are conditionally uncorrelated.

Conditional independence is a probabilistic approach to causality while correlation is not. A comprehensive account of conditional independence is given in Dawid (1979).

Odds, logit Transform, and Logistic Function

In stochastics, an odds (in favor) O is defined as the ratio of the probabilities of an event and its complement. The logit transform is defined as the natural logarithm of an odds. Thus, for a random indicator variable T where $T = 1$ indicates presence and $T = 0$ indicates absence of some event, the logit transform of the probability P_T is defined as

$$\text{logit } P_T = \ln O_T = \ln \frac{P_T(1)}{P_T(0)} = \ln \frac{P_T(1)}{1 - P_T(1)} \quad (6)$$

provided that $P_T(0) \neq 0$. Odds and logit transform are depicted in Fig. 1.

The logistic function is defined as

$$A(z) = \frac{1}{1 + \exp(-z)}, \quad z \in \mathbb{R}. \quad (7)$$

Logit transform and logistic function are mutually inverse. The graph of the latter is shown in Figs. 1 and 2.

Estimating Probabilities

Odds, logit transform, and logistic function are instrumental in resolving the problem of estimating probabilities.

Let T denote a random indicator variable often referred to as target variable T coded such that the value $T = 1$ indicates the occurrence of an appealing event or the presence of an interesting phenomenon, for example, a certain mineralization. Let B_ℓ , $\ell = 1, \dots, m$, $m \geq 1$, denote a collection of categorical or real-valued continuous random predictor variables providing favorable or unfavorable conditions for the event $T = 1$. What are reasonable ways to estimate $P_{T|B_0 \otimes B_\ell}(1|1, \dots, b_\ell, \dots)$,

that is, the conditional probability of the event $T = 1$ given predictors B_ℓ , $\ell = 1, \dots, m$, and $B_0 \equiv 1$?

Logistic Regression

Logistic regression in its basic linear form statistically models, that is, estimates the logit transform $\text{logit } P_{T|\otimes_{\ell=0}^m B_\ell}$ of the conditional probability of a random indicator target variable T to be equal 1 given categorical or real-valued continuous predictor variables B_ℓ , $\ell = 1, \dots, m$, $m \geq 1$, by a linear combination of the predictor variables plus a constant, the intercept $B_0 \equiv 1$, that is, with $\otimes_{\ell=0}^m B_\ell = (B_0, B_1, \dots, B_m)^T$

$$\text{logit } \widehat{P}_{T|\otimes B_\ell} = \beta_0 + \sum_{\ell} \beta_{\ell} B_{\ell}, \quad (8)$$

where the $\hat{\cdot}$ denotes the estimator. In practical applications the coefficients β_{ℓ} of the linear combination are estimated by $\hat{\beta}_{\ell}$ from data

$$\text{logit } P_{T|\otimes B_\ell}(\widehat{1}|1, \dots, b_\ell, \dots) = \hat{\beta}_0 + \sum_{\ell} \hat{\beta}_{\ell} b_{\ell} \quad (9)$$

applying maximum likelihood estimation, and usually determined numerically by solving the corresponding system of nonlinear equations by application of iteratively reweighted least squares. Significance tests exist to check the reliability of the model.

Since logit transform and logistic function are inverse, the conditional probability of $T = 1$ given predictors $B_0, B_1, \dots, B_m$ is given by

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Fig. 1 Graphs of odds O associated to probabilities P (left), and logit transform of probabilities P . (From Schaeben (2014b))

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Fig. 2 Graphs of the sigmoidal logistic function $\Lambda(z)$ (left) and $\Lambda(32z)$ (right), indicating its fast convergence to the Heaviside function. (From Schaeben (2014b))

$$P_{T|\otimes_{\ell} B_{\ell}}(\widehat{1}|1, \dots) = \Lambda\left(\beta_0 + \sum_{\ell} \beta_{\ell} B_{\ell}\right) \quad (10)$$

Linear logistic regression is optimum, that is, exact, as the estimator agrees with the true conditional probability, if the predictors B_{ℓ} are indicator or categorical random variables and jointly conditionally independent given the target variable T (Schaeben 2014a).

A linear logistic regression model can be generalized into nonlinear logistic regression models when interaction terms, that is, products of predictors, are included

$$\begin{aligned} \text{logit} \widehat{P_{T|\otimes_{\ell} B_{\ell}}} &= \beta_0 + \sum_{\ell} \beta_{\ell} B_{\ell} \\ &+ \sum_{\ell_i, \dots, \ell_j} \beta_{\ell_i, \dots, \ell_j} B_{\ell_i} \dots B_{\ell_j}. \end{aligned} \quad (11)$$

Then

$$\widehat{P_{T|\otimes_{\ell} B_{\ell}}} = \Lambda\left(\beta_0 + \sum_{\ell} \beta_{\ell} B_{\ell} + \sum_{\ell_i, \dots, \ell_j} \beta_{\ell_i, \dots, \ell_j} B_{\ell_i} \dots B_{\ell_j}\right). \quad (12)$$

For indicator or categorical random predictor variables, proper interaction terms compensate any lack of conditional independence exactly. Then logistic regression with interaction terms is optimum, that is, the estimator agrees with the true conditional probability (Schaeben 2014a).

Given $m \geq 2$ predictor variables $B_{\ell} \neq 1$, $\ell = 1, \dots, m$, there is a total of $\sum_{\ell=2}^m \binom{m}{\ell} = 2^m - (m+1)$ possible interaction terms. To compensate a violation of conditional independence the interaction term $B_{\ell_1} \otimes \dots \otimes B_{\ell_k}$, $k \leq m$, is actually required, if $B_{\ell_1}, \dots, B_{\ell_k}$ are not jointly conditionally independent given T . Thus, recognizing which variables or interaction terms cause violations of conditional independence becomes

essential because the total number 2^m of all possible terms would have to be reasonably smaller than the sample size n to be a practically feasible model.

Logistic regression seems to have been systematically developed first by Berkson (1944), a standard reference for modern applied logistic regression is Hosmer et al. (2013), and a recent publication that focused on its application to prospectivity modeling is Kost (2020). Logistic regression is a method of statistical learning, the focus of which is inference of interpretable models. Often, the major progress of understanding and knowledge takes place by a trial-and-error approach to select the most powerful predictor variables or products thereof advancing possible inference most efficiently.

Weights of Evidence

Without any additional mathematical/statistical modeling assumption Bayes' theorem for the random indicator target variable T and several random indicator variables B_{ℓ} , $\ell = 1, \dots, m$, $m \geq 2$, gives

$$\begin{aligned} \text{logit} P_{T|\otimes_{\ell=1}^m B_{\ell}}(1|\dots) &= \text{logit} P_{T|\otimes_{\ell=1}^{m-1} B_{\ell}}(1|\dots) \\ &+ \ln F_m \end{aligned} \quad (13)$$

$$= \text{logit} P_T(1) + \sum_{\ell=1}^m \ln F_{\ell} \quad (14)$$

with

$$F_{\ell} = \frac{P_{B_{\ell}|\otimes_{i=0}^{\ell-1} B_i \otimes T}(\cdot|1, \dots, 1)}{P_{B_{\ell}|\otimes_{i=0}^{\ell-1} B_i \otimes T}(\cdot|1, \dots, 0)}, \ell = 1, \dots, m. \quad (15)$$

Assuming joint conditional independence of $B_1, \dots, B_m$ given T simplifies the factors F_{ℓ} to

$$F_\ell = \frac{P_{B_\ell|T}(\cdot|1)}{P_{B_\ell|T}(\cdot|0)}, \ell = 1, \dots, m. \quad (16)$$

Explicitly distinguishing the two possible outcomes for each B_ℓ and taking logarithms results in the weights of evidence

$$W_\ell(i) = \ln \frac{P_{B_\ell|T}(i|1)}{P_{B_\ell|T}(i|0)}, i = 0, 1, \quad (17)$$

and their contrasts

$$C_\ell = W_\ell(1) - W_\ell(0), \ell = 1, \dots, m, \quad (18)$$

and eventually in the log-linear form of Bayes' theorem referred to as the method of "weights of evidence" in geology

$$\begin{aligned} \text{logit } P_{T|\otimes_\ell B_\ell}(1|\dots) &= C_0 + \sum_\ell C_\ell B_\ell \\ &= C_0 + \sum_{\ell: B_\ell \neq 0} C_\ell B_\ell \end{aligned} \quad (19)$$

$$P_{T|\otimes_\ell B_\ell}(1|\dots) = \mathcal{A} \left(C_0 + \sum_{\ell: B_\ell \neq 0} C_\ell B_\ell \right) \quad (20)$$

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Fig. 3 Classification induced by fitted logistic regression models. Realizations of B_1 , B_2 are generated according to a bivariate normal distribution with mean 0 and standard deviation 1. They are plotted in the plane spanned by B_1 and B_2 . Realizations of the indicator random variable T are generated according to the binomial distribution $B(1, p)$ with (i) p as provided by the linear model, that is, $p = \mathcal{A}(-2 - 2B_1 + 2B_2)$, and (ii) p as provided by the nonlinear model including the interaction term, that is,

$p = \mathcal{A}(-2 - 2B_1 + 2B_2 + 2B_1B_2)$, respectively. Linear logistic regression analysis applied to simulated data of model (i) yields the two classes separated by the straight line shown at the top left; linear logistic regression analysis applied to simulated data of model (ii) yields the two classes separated by the straight line shown at the top right; non-linear logistic regression analysis including the interaction term B_1B_2 applied to simulated data of model (ii) yields the two classes separated by the curve shown at the bottom center.

with $C_0 = \logit P_T(1) + \sum_{\ell} W_{\ell}(0)$. Thus, weights of evidence is first of all a straightforward application of Bayes' theorem. In practical applications the weights, that is, the involved conditional probabilities, are estimated by relative frequencies, that is, by counting.

Weights of evidence were introduced by (Good 1950, 1968), and with respect to potential modeling or prospectivity modeling into geology by Bonham-Carter et al. (1989) and Agterberg et al. (1990).

Relationship of Linear Logistic Regression and Weights of Evidence

Comparing Eq. (19) and Eq. (8) reveals with $\beta_0 = C_0$ and $\beta_{\ell} = C_{\ell}$, $\ell = 1, \dots, m$, immediately that weights of evidence is the special case of logistic regression for jointly conditionally independent random indicator predictor variables (Schaeben 2014b).

Additional light is shed on logistic regression and weights of evidence, respectively, from a classification point of view. Thresholding of estimated conditional probabilities may be applied to design a $\{0,1\}$ classification, usually with respect to the estimator of the conditional median of the target variable

$$\hat{T}_{0.5} = \begin{cases} 0 & \text{if } \hat{P}_{T|\otimes_{\ell} B_{\ell}}(1|\dots) \leq 0.5, \\ 1 & \text{otherwise.} \end{cases} \quad (21)$$

For logistic regression the locus for which $\hat{P}_{T|\otimes_{\ell} B_{\ell}}(1|\dots) = 0.5$ is given by setting

$$\hat{\beta}_0 + \sum_{\ell} \hat{\beta}_{\ell} B_{\ell} + \sum_{\ell_i, \dots, \ell_j} \hat{\beta}_{\ell_i, \dots, \ell_j} B_{\ell_i} \otimes \dots \otimes B_{\ell_j} = 0. \quad (22)$$

As Fig. 3 illustrates, if all interaction terms vanish, that is, in the case of linear logistic regression, Eq. (22) represents a hyperplane in the space spanned by the contributing B_{ℓ} ; in the general nonlinear case Eq. (22) represents a curved surface separating the two classes.

The method of weights of evidence cannot include interaction terms, because along the derivation from Bayes' general theorem for several random indicator variables, Eq. (14), to weights of evidence, Eq. (17), they are made to vanish by the very assumption of joint conditional independence. Therefore the two classes of the classification induced by weights of evidence are always separated by a hyperplane.

Another way of comparing methods of estimating probabilities or conditional probabilities is by precision-recall curves (PR) rather than receiver operating characteristic (ROC) curves (Davis and Goadrich 2006) because PR curves are more appropriate if the target event $T = 1$ is a rare event as often experienced in practical applications.

Practical Example with Fabricated Data

One hundred triplets of realizations (b_{1i}, b_{2i}, t_i) , $i = 1, \dots, 100$, of random indicator variables (B_1, B_2, T) are assigned to 100 pixels arranged in a (10×10) -array of pixels of digital map images. A specific assignment is depicted in Fig. 4 and referred to as dataset RANKIT.

The assignment could be different without changing the ordinary statistics; however, spatial statistics as captured by a variogram would be different (Schaeben 2014b). Obviously, logistic regression and weights of evidence are nonspatial methods, as they are independent of any specific spatial assignment.

Testing the null hypothesis of joint conditional independence with the standard log-likelihood ratio test yields

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Fig. 4 Spatial distribution of two indicator predictor variables B_1 , B_2 , and the indicator target variable T of the dataset RANKIT. (From Schaeben (2014b))

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Table 1 Comparison of predicted conditional probabilities for various methods applied to the training dataset RANKIT

$\hat{P}_{T B_1 \otimes B_2}(1 \cdot)$	Elementary counting	WofE	Linear LogReg	Nonlinear LogReg
$B_1 = 1, B_2 = 1$	0.25000	0.58636	0.64055	0.25000
$B_1 = 1, B_2 = 0$	0.37500	0.26875	0.27736	0.37500
$B_1 = 0, B_2 = 1$	0.31250	0.20156	0.21486	0.31250
$B_1 = 0, B_2 = 0$	0.03125	0.06142	0.05565	0.03125

Logistic Regression, Weights of Evidence, and the Modeling Assumption of Conditional Independence, Fig. 5 Spatial distribution of predicted $\hat{P}(T=1|B_1B_2)$ for the training dataset RANKIT according to elementary estimation (top left), logistic regression with

interaction term (top right), weights-of-evidence (bottom left), and logistic regression without interaction term (bottom right). (From Schaben (2014b))

$p = 0.06443468$ and suggests the decision to reject the null hypothesis (Schaeben 2014b).

The fitted models of weights of evidence, linear logistic regression without interaction term, and nonlinear logistic regression with interaction term read explicitly as follows:

$$\begin{aligned} \text{WofE} : \hat{P}_{T|B_1 \otimes B_2}(1|..) \\ = A(-2.726 + 1.725 B_1 + 1.349 B_2) \end{aligned} \quad (23)$$

$$\begin{aligned} \text{linLogReg} : \hat{P}_{T|B_1 \otimes B_2}(1|..) \\ = A(-2.831 + 1.874 B_1 + 1.535 B_2) \end{aligned} \quad (24)$$

$$\begin{aligned} \text{non - linLogReg} : \hat{P}_{T|B_1 \otimes B_2}(1|..) \\ = A(-3.434 + 2.923 B_1 + 2.646 B_2 - 3.233 B_1 B_2) \end{aligned} \quad (25)$$

Since the mathematical modeling assumption of conditional independence is violated, only logistic regression with interaction terms yields a proper model and predicts the conditional probabilities almost exactly.

The results of weights of evidence, logistic regression with or without interaction terms, applied to the fabricated dataset RANKIT are summarized in Table 1, and Fig. 5 depicts the results of dataset RANKIT.

The example illustrates that application of weights of evidence even though the predictor variables are not jointly conditionally independent of the target variable corrupts its estimated conditional probabilities and assigns their largest values to false locations, that is, false pixels of the digital map image. Logistic regression is the canonical generalization of weights of evidence as it exactly compensates lack of joint conditional independence of random indicator predictor variables by including interaction terms corresponding to the actual violations of joint conditional independence. For random indicator predictor variables logistic regression is optimum. Thus there is no need for ad hoc recipes to fix weights of evidence corrupted by lack of joint conditional independence. Eventually logistic regression is not restricted to random indicator predictor variables, the predictors may be real-valued continuous random variables, rendering their transform to indicator predictors by thresholding as required by weights of evidence dispensable.

Conclusions

Logistic regression provides a functional model to estimate conditional probabilities. The regression coefficients are determined according to the maximum likelihood method

applying the truncated iteratively re-weighted least squares algorithm. If the functional form is restricted to linear dependencies only, and if the predictor variables are assumed to be binary and jointly conditionally independent given the binary target variable, then logistic regression largely simplifies to the formula of Bayes' theorem for several variables referred to as weights of evidence; its numerics is largely simplified to counting as means to estimate probabilities from empirical frequencies of events.

Log-Likelihood Ratio Test

Alejandro C. Frery
School of Mathematics and Statistics, Victoria University of Wellington, Wellington, New Zealand

Definition

The log-likelihood ratio test contrasts two parametric models, of which one is a subset or restriction of the other.

Consider the random sample $\mathbf{X} = (X_1, X_2, \dots, X_n)$ from the model characterized by the distribution $\mathcal{D}(\theta)$, with $\theta \in \Theta \subset \mathbb{R}^p$. One may be interested in checking the null hypothesis that the model for the data belongs to a subset $\mathcal{H}_0 : \theta \in \Theta_0 \subset \Theta$ of all the possible models, versus the alternative $\mathcal{H}_1 : \theta \in \Theta_1 = \Theta \setminus \Theta_0$.

An approach consists in comparing the likelihoods of the sample under $\mathcal{H}_0$ and under the unrestricted model. The comparison can be made by computing the ratio of the likelihoods, or the logarithm of such ratio.

Adapting the definition given by Casella and Berger (2002), we will say that a likelihoods ratio test for contrasting $\mathcal{H}_0 : \theta \in \Theta_0$ against $\mathcal{H}_1 : \theta \in \Theta \setminus \Theta_0$ is any test that rejects $\mathcal{H}_0$ if

$$\frac{\sup_{\theta \in \Theta} L(\theta; \mathbf{X})}{\sup_{\theta \in \Theta_0} L(\theta; \mathbf{X})} > c', \quad (1)$$

where $L(\theta; \mathbf{X})$ is the likelihood of the parameter θ for the sample $\mathbf{X}$ and c' is a constant that depends on the desired significance.

Assume the maximum likelihood estimator for the problem exists. The numerator in Eq. (1) is the likelihood over all possible values of the parameter, which is maximized by the maximum likelihood estimator $\hat{\theta}$. The denominator in Eq. (1) is the maximum likelihood estimator restricted to Θ_0 ; denote it $\hat{\theta}_0$. Inequality (Eq. 1) becomes

$$\frac{L(\hat{\theta}; \mathbf{X})}{L(\hat{\theta}_0; \mathbf{X})} > c', \quad (2)$$

Since both numerator and denominator are positive,

$$\begin{aligned} \log \frac{L(\hat{\theta}; \mathbf{X})}{L(\hat{\theta}_0; \mathbf{X})} &= \log L(\hat{\theta}; \mathbf{X}) - \log L(\hat{\theta}_0; \mathbf{X}) \\ &= \ell(\hat{\theta}; \mathbf{X}) - \ell(\hat{\theta}_0; \mathbf{X}) > \log c' = c \end{aligned}$$

is the same test, in which $\ell(\theta; \mathbf{X})$ is the reduced log-likelihood of θ for $\mathbf{X}$.

We will see two examples before completing the theory of likelihood ratio tests.

Testing Under the Multinomial Distribution

Consider the Example 12.6.6 from Lehman and Romano (2005). The random sample $\mathbf{X} = (X_1, X_2, \dots, X_n)$ follows a multinomial distribution, i.e., each random variable may assume one of $k + 1$ values with probability $\Pr(X = j) = p_j$,

$j \in \{1, 2, \dots, k + 1\}$. The parameter space is $\Theta = \{\mathbf{p} = (p_1, p_2, \dots, p_k) : p_j \geq 0 \text{ and } \sum_{j=1}^k p_j \leq 1\}$. We want to test the null hypothesis that we know the k probabilities that index the distribution, i.e., $\mathcal{H}_0 : \{p_i = \pi_i, i \in \{1, 2, \dots, k\}\}$, since $p_{k+1} = 1 - \sum_{j=1}^k p_j$. The parameter space in the null hypothesis is the point $\Theta_0 = \boldsymbol{\pi} = (\pi_1, \pi_2, \dots, \pi_k)$, which is known. Denote Y_i the number of observations in $\mathbf{X}$ that are equal to i . The likelihood of the sample is

$$\begin{aligned} L(\mathbf{p}; \mathbf{X}) &= \frac{n!}{Y_1! Y_2! \dots Y_{k+1}!} p_1^{Y_1} p_2^{Y_2} \dots p_{k+1}^{Y_{k+1}} \\ &= \frac{n!}{Y_1! Y_2! \dots Y_k! (n - \sum_{j=1}^k Y_j)!} p_1^{Y_1} p_2^{Y_2} \dots \\ &\quad p_k^{Y_k} \left(1 - \sum_{j=1}^k p_j\right)^{n - \sum_{j=1}^k Y_j}, \end{aligned}$$

and the maximum likelihood estimator in Θ is the vector of proportions

$$\begin{aligned} \hat{\mathbf{p}} &= (\hat{p}_1, \hat{p}_2, \dots, \hat{p}_k, \widehat{p_{k+1}}) \\ &= \left(\frac{Y_1}{n}, \frac{Y_2}{n}, \dots, \frac{Y_k}{n}, 1 - \frac{\sum_{j=1}^k Y_j}{n}\right). \end{aligned}$$

The likelihoods ratio test statistic is

$$\frac{L(\hat{\mathbf{p}}; \mathbf{X})}{L(\boldsymbol{\pi}; \mathbf{X})} = \frac{\hat{p}_1^{Y_1} \hat{p}_2^{Y_2} \dots \widehat{p_{k+1}}^{Y_{k+1}}}{\pi_1^{Y_1} \pi_2^{Y_2} \dots \pi_{k+1}^{Y_{k+1}}} = \left(\frac{\hat{p}_1}{\pi_1}\right)^{Y_1} \left(\frac{\hat{p}_2}{\pi_2}\right)^{Y_2} \dots \left(\frac{\widehat{p_{k+1}}}{\pi_{k+1}}\right)^{Y_{k+1}}.$$

Both numerator and denominator are positive, and the latter, being constrained, cannot be larger than the former. Taking the logarithm, we obtain the log-likelihoods ratio:

$$\ell(\hat{\mathbf{p}}; \mathbf{X}) - \ell(\boldsymbol{\pi}; \mathbf{X}) = \sum_{j=1}^{k+1} Y_j \log \frac{\hat{p}_j}{\pi_j} = n \sum_{j=1}^{k+1} \hat{p}_j \log \frac{\hat{p}_j}{\pi_j}. \quad (3)$$

Finally, the test statistic

$$R_n(\mathbf{X}) = 2[\ell(\hat{\mathbf{p}}; \mathbf{X}) - \ell(\boldsymbol{\pi}; \mathbf{X})]$$

becomes useful by knowing that, under $\mathcal{H}_0$, it is asymptotically a χ_k^2 -distributed random variable. Notice that Eq. (3) is closely related to the Kullback-Leibler divergence between $\hat{\mathbf{p}}$ and $\boldsymbol{\pi}$.

We now illustrate this example with simulations. Fixing $\boldsymbol{\pi} = (0.3, 0.2, 0.1, 0.25, 0.15)$, we obtain samples of size $n \in \{50, 100, 200, 300, 400, 500, 10^3, 10^4\}$ from this distribution, then we compute $\hat{\mathbf{p}}$ and obtain R_n . Since R_n is asymptotically distributed as χ_4^2 , the asymptotic values of the

Log-Likelihood Ratio Test, Fig. 1 R_n samples boxplots under $\mathcal{H}_0$ for $n \in \{50, 100, 200, 300, 400, 500, 10^3, 10^4\}$, along with the mean (Eq. 4), median, and 95% and 99% quantiles (dashed lines) of a χ_4^2 -distributed random variable

mean, (approximate) median, and quantiles of order 95% and 99% are, respectively, 4, 3.36, 9.49, and 13.28. Figure 1 shows the boxplots of these test statistics after 300 independent replications for each situation, along with these values. Notice that there is good agreement between the sample values and asymptotic quantities.

Testing Under the Normal Distribution

Consider the situation in which $\mathbf{X}$ is a collection of normal random variables with unknown mean $\mu \in \mathbb{R}$ and variance $\sigma^2 > 0$. The parameter space is $(\mu, \sigma^2) \in \Theta = \mathbb{R} \times \mathbb{R}_+$. The densities are of the form $f(x; \mu, \sigma^2) = (2\pi\sigma^2)^{-1/2} \exp \{-(-x - \mu)^2/(2\sigma^2)\}$, so the reduced likelihood and log-likelihood are, respectively,

$$L(\mu, \sigma^2; \mathbf{X}) = (\sigma^2)^{-n/2} \exp \left\{ -\frac{1}{2\sigma^2} \sum_{i=1}^n (X_i - \mu)^2 \right\}, \quad \text{and} \quad (4)$$

$$\ell(\mu, \sigma^2; \mathbf{X}) = -\frac{n}{2} \log \sigma^2 - \frac{1}{2\sigma^2} \sum_{i=1}^n (X_i - \mu)^2. \quad (5)$$

The maximum likelihood estimator of (μ, σ^2) is, thus, the pair $(\hat{\mu}, \hat{\sigma}^2)$ given by

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^n X_i, \quad \text{and} \quad \hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^n (X_i - \hat{\mu})^2. \quad (6)$$

The estimator given in Eq. (6) maximizes both Eqs. (4) and (5) in the unrestricted parameter space Θ . Assume now we are interested in testing the null hypothesis $\mathcal{H}_0: \mu = 0$. The parameter space under $\mathcal{H}_0$ is $\Theta_0 = \mathbb{R}_+$, and we now need to estimate σ^2 under the restriction $\mu = 0$, which amounts to computing

$$\hat{\sigma}_0^2 = \frac{1}{n} \sum_{i=1}^n X_i^2.$$

We may now compare the models with the difference of the log-likelihoods:

$$R_n(\mathbf{X}) = \ell(\hat{\mu}, \hat{\sigma}^2; \mathbf{X}) - \ell(\hat{\sigma}_0^2; \mathbf{X}).$$

Figure 2 shows the boxplots of 300 independent replications for each situation of this test statistics. The situations here considered are $n = 100$, $\mathcal{H}_0$, i.e., $N(0, 1)$ samples, and deviations from $\mathcal{H}_0$ which consist of sampling from $N(\Delta, 1)$, and $\Delta \in \{1/10, 2/10, 3/10, 4/10, 5/10\}$. Notice that the log-likelihoods ratio samples vary around zero, while central value of the others increases with Δ .

Log-Likelihood Ratio Test,

Fig. 2 R_n samples boxplots under $\mathcal{H}_0$ for $\Delta \in \{0, 1/10, 2/10, 3/10, 4/10, 5/10\}$

**Asymptotic Distribution**

The result that makes the likelihoods ratio test widely usable is the following. Consider the test statistic

$$\Lambda = 2 \log \frac{L(\hat{\theta}; \mathbf{X})}{L(\hat{\theta}_0; \mathbf{X})}.$$

Wilks (1938) proved that, under mild conditions and under $\mathcal{H}_0$, this test statistic has asymptotically a χ_r^2 distribution with r degrees of freedom, in which r is the difference of dimensions between Θ and Θ_0 .

Summary

Likelihoods ratio tests are very general and useful for contrasting a variety of hypotheses.

Lognormal Distribution

Glòria Mateu-Figueras¹ and Ricardo A. Olea²

¹Department of Computer Science, Applied Mathematics and Statistics, University of Girona, Girona, Spain

²Geology, Energy and Minerals Science Center, U.S. Geological Survey, Reston, VA, USA

Definition

A positive random variable X is lognormally distributed with two parameters μ and σ^2 if $Y = \ln(X)$ follows a normal distribution with mean μ and variance σ^2 . The lognormal distribution is denoted by $\Lambda(\mu, \sigma^2)$ and its probability density function is (Everitt and Skrondal 2010):

$$f(x) = \frac{1}{x \cdot \sigma \cdot \sqrt{2 \cdot \pi}} \cdot \exp \left[-\frac{(\ln x - \mu)^2}{2 \cdot \sigma^2} \right], 0 < x < \infty. \quad (1)$$

Note that the sampling space of X is the positive side of the real axis. By construction, the main property of the lognormal distribution is that $\ln(X)$ follows a normal distribution with mean μ and variance σ^2 , and, conversely, the exponential form $\exp(Y)$ of any normal distribution is a lognormal distribution (Fig. 1). Note that in all cases the lognormal density (Fig. 1a) is unimodal and positively skewed.

Lognormal Distribution, Fig. 1 (a) linear scale; (b) logarithmic scale

Historical Remarks and Properties

The normal distribution has long been associated with the modeling of additive errors. The roots of the formulation of the lognormal distribution go back to 1879 to the efforts of Francis Galton and Donald McAlister finding an adequate model for studying multiplicative errors (Galton 1879; McAlister 1879). In fact, given $X_1, X_2, \dots, X_n$ independent and strictly positive random variables, the product

$$\prod_{j=1}^n X_j \quad (2)$$

tends to a lognormal distribution as n tends to infinity, as confirmed by the central limit theorem applied to the respective logarithms.

Later, different properties in the theory of probability were used to explain the genesis of the lognormal distribution. The most important are the Law of Proportionate Effect and the Theory of Breakage. The Law of Proportionate effect can be formulated as (Gibrat 1930, 1931)

$$X_j = X_{j-1}(1 + \varepsilon_j), j = 1, \dots, n, \quad (3)$$

where $X_0, X_1, \dots, X_n$ is a sequence of random variables and $\varepsilon_1, \dots, \varepsilon_n$ are mutually independent and identically distributed random variables, also statistically independent of the set $\{X_j\}$. Note that, at the j th step, the change in the variate is a random proportion of the value X_{j-1} . From Eq. 3 we obtain

$$X_n = X_0 \prod_{j=1}^n (1 + \varepsilon_j). \quad (4)$$

Assuming that the absolute value of ε_j is small compared with 1, and using the Taylor expansion of $\ln(1 + x)$, we obtain

$$\ln(X_n) = \ln(X_0) + \sum_{j=1}^n \varepsilon_j. \quad (5)$$

Finally, using the central limit theorem, we conclude that $\ln(X_n)$ is asymptotically normally distributed and, consequently, X_n is asymptotically lognormally distributed.

The Theory of Breakage, used in particle size statistics, is essentially an inverse application of the Theory of Proportionate Effect (Crow and Shimizu 1988). In fact, consider that X_0 is the initial mass of a particle subject to a breakage process, that is, successive independent subdivisions. Let X_j be the mass of the particle in the j th step. Then, it can be proven that the distribution of X_n is asymptotically lognormal. This theory is very similar to the theory of classification, where the number of items classified in some homogeneity groups can be approximately lognormal distributed.

As can be observed in Fig. 1, it seems that the distribution has two shapes. For large variances the density function shows an exponential decline. Otherwise, the density function is peaked and asymmetric. In fact, the density function (Eq. 1) has two points of inflection at $\exp(\mu - \frac{3}{2}\sigma^2 \pm \frac{1}{2}\sigma\sqrt{\sigma^2 + 4})$ (Johnson et al. 1994), but for large values of the parameter σ^2 these points are too close to the origin to be observed separately.

Also, the lognormal model has been applied in an empirical way to fit many variables. So, there are both theoretical and empirical arguments in support of the existence of natural attributes and phenomena following the lognormal distribution. Aitchison and Brown (1957) and Krige (1978) also made valuable contributions to the use and understanding of the lognormal distribution.

Two characteristics of the lognormal distribution that have made it a useful tool in the earth sciences, economics, and population growth are the impossibility of taking negative values and its long upper tail (positive skewness). In the earth sciences, it is used to model the metal content of rock chips in a mineral deposit, the size of oil and gas pools, and in the lognormal kriging method for local estimation. The reader can find a large number of examples and references in Crow and Shimizu (1988), Aitchison and Brown (1957), or Johnson et al. (1994).

Statistics

Given $X \sim \Lambda(\mu, \sigma^2)$, the r -th moment of X about the origin is

$$\exp\left(r\mu + \frac{1}{2}r^2\sigma^2\right) \quad (6)$$

obtained using the properties of the moment generating function of the normal distribution, since $Y = \ln(X)$. From Eq. 6, we can obtain the mean and the variance as

$$\text{Mean} = \exp\left(\mu + \frac{1}{2}\sigma^2\right) \quad (7)$$

$$\text{Variance} = \exp(2 \cdot \mu + \sigma^2) \cdot (\exp(\sigma^2) - 1). \quad (8)$$

The shape factors, the coefficient of skewness, and the coefficient of kurtosis, are

$$\text{Skewness} = (\exp(\sigma^2) + 2) \cdot (\exp(\sigma^2) - 1)^{1/2} \quad (9)$$

$$\begin{aligned} \text{Kurtosis} &= 3 \cdot \exp(2 \cdot \sigma^2) + 2 \cdot \exp(3 \cdot \sigma^2) \\ &+ \exp(4 \cdot \sigma^2) - 3. \end{aligned} \quad (10)$$

Eq. 10 is zero when the distribution follows a normal distribution. From the expressions Eq. 9 and Eq. 10, it is clear that the skewness and the kurtosis increase with the value of σ^2 .

Other measures of interest are

$$\text{Median} = \exp(\mu) \quad (11)$$

$$\text{Mode} = \exp(\mu - \sigma^2). \quad (12)$$

As can be observed from the expressions, the relative position of the mean (Eq. 7), median (Eq. 11), and mode (Eq. 12) is $\text{Mode} < \text{Median} < \text{Mean}$, emphasizing again the positive skewness of the distribution.

Given $X \sim \Lambda(\mu, \sigma^2)$, the properties of the logarithmic function and the properties of the normal distribution allow proving that $(1/X) \sim \Lambda(-\mu, \sigma^2)$, $cX \sim \Lambda(\mu + \ln c, \sigma^2)$ for $c > 0$ and $X^a \sim \Lambda(a\mu, a^2\sigma^2)$ for $a \neq 0$.

Estimation

Given a sample from a $\Lambda(\mu, \sigma^2)$ distribution, the estimation of the parameters μ and σ^2 is relatively straightforward. As the logarithm of the variable is normally distributed, one must take logarithms of all values and proceed to estimate parameters μ and σ^2 using the well-known estimators for the mean and the variance of any sample. The same is true if we want to obtain exact confidence intervals for parameters μ and σ^2 . The main statistics of the lognormal distribution can be obtained by applying Eqs. 7–12.

Certainly, the mean and the variance of a lognormal random variable can be estimated applying directly the conventional estimators available for samples, that is, without making any logarithmic transformation. However, it can be proved that such estimators and their confidence intervals may be inefficient and suboptimal. In the literature we can find a large number of works seeking the best estimators. Finney (1941) proposes an unbiased minimum variance estimator for the mean using the Finney function. This solution is difficult to apply because it involves an infinite series, which Clark and Harper (2000) tabulated in an effort to simplify the application. Taraldsen (2005) derives a modified maximum likelihood estimator which approximates the Finney approach. Taraldsen (2005) and Tang (2014) compare several methods to estimate the mean of the lognormal distribution offering some numerical examples and simulations for appreciating the differences. Ginos (2009) does it for both the mean and the variance.

Other Forms of the Distribution

Mateu-Figueras and Pawlowsky-Glahn (2008) have proposed to consider the multiplicative structure of the positive real line and work with the density function with respect to the resulting multiplicative measure. The result is a density different from Eq. 1 but the same law of probability is obtained. Some interesting differences are obtained in the moments providing a justification for using the geometric mean to represent the first moment. This approach was implicit in the original definition of the lognormal distribution by McAlister (1879).

Two other expanded forms of the lognormal distribution have been postulated for accommodating special needs. In the three-parameter lognormal distribution, a value θ is subtracted from Eq. 1, so that now the sampling domain is shifted, starting at θ :

$$f(x) = \frac{1}{(x - \theta) \cdot \sigma \cdot \sqrt{2 \cdot \pi}} \cdot \exp \left[-\frac{(\ln(x - \theta) - \mu)^2}{2 \cdot \sigma^2} \right], \theta < x < \infty. \quad (13)$$

The three-parameter lognormal has been extensively studied by Yuan (1933). The addition of the shift parameter θ gives the model more flexibility but increases the difficulties of estimating parameters. It is an important model in many scientific disciplines. For example, in hydrology, it is used to model seasonal flow volumes, rainfall intensity or soil water retention (Singh 1998).

The other expanded form is the truncated lognormal distribution (Zaninetti 2017):

$$f(x) = \frac{\sqrt{2} \cdot \exp \left[-\frac{(\ln x - \mu)^2}{2 \cdot \sigma^2} \right]}{-\sqrt{\pi} \cdot \sigma \cdot x \cdot \left(\operatorname{erf} \left(\frac{\ln x_l - \mu}{\sqrt{2} \cdot \sigma} \right) - \operatorname{erf} \left(\frac{\ln x_u - \mu}{\sqrt{2} \cdot \sigma} \right) \right)}, x_l < x < x_u, \quad (14)$$

where x_l and x_u are the lower and upper truncation boundaries, respectively, and erf is the function:

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \cdot \int_0^x \exp(-t^2) dt. \quad (15)$$

The truncated lognormal distribution has been used in the assessment of the sizes of undiscovered oil and gas accumulations (Attanasi and Charpentier 2002).

If there are problems with the $(0, +\infty)$ boundaries of the lognormal distribution, in general it is better to work with other distributions with fixed and flexible boundaries, such as the beta distribution (Olea 2011).

The Multivariate Lognormal Distribution

Although not so popular as the univariate distribution, we have the multivariate version of the lognormal distribution. Given $\mathbf{Y} = (Y_1, \dots, Y_n) = (\ln(X_1), \dots, \ln(X_n))$ a multivariate normal distribution with parameters vector $\boldsymbol{\mu}$ and matrix $\boldsymbol{\Sigma}$, the distribution of the positive random vector $\mathbf{X} = (X_1, \dots, X_n)$ is multivariate lognormal and its density function is

$$f(x_1, \dots, x_n) = \frac{1}{(2\pi)^{n/2} |\boldsymbol{\Sigma}|^{1/2} x_1 \cdots x_n} \exp \left[-\frac{1}{2} (\ln \mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\ln \mathbf{x} - \boldsymbol{\mu}) \right], \mathbf{x} \in \mathbb{R}_+^n. \quad (16)$$

Summary and Conclusions

The lognormal distribution matches the tendency of numerous geological attributes that are positively defined and positively skewed, thus highlighting its importance in earth sciences modeling. Also, it is a distribution that has applications supported by theoretical arguments. It is a congenial model due to the relationship with the normal distribution. A large number of publications deal with the problem to directly find consistent estimators and exact confidence intervals for the mean and the variance.

Lorenz, Edward Norton

Kerry Emanuel
Lorenz Center, Massachusetts Institute of Technology,
Cambridge, MA, USA

Fig. 1 Edward Norton Lorenz (1917–2008), courtesy of Prof. Kerry Emanuel

Biography

Edward Norton Lorenz, a mathematician and meteorologist, is best known for having demonstrated that the macroscopic universe is almost certainly not predictable beyond fundamental time horizons, putting an end to the notion of a clockwork universe. His work had the most immediate application to weather prediction but has also had a strong influence on mathematics and physics.

This is a condensed version of a more extensive biography of Lorenz, which the author published with the National Academy of Sciences (Emanuel 2011)

Lorenz was born in West Hartford, Connecticut, on 23 May 1917, to Edward Henry Lorenz, a mechanical engineer, and Grace Lorenz (née Norton), a school teacher. As a boy he enjoyed solving mathematical puzzles with his father and from his mother learned to love board and card games.

Lorenz entered Dartmouth College as a mathematics major in 1934. In 1938 he entered the graduate school of the mathematics department at Harvard, but his mathematical training was interrupted by World War II. He contributed to the war effort by training in meteorology at the Massachusetts Institute of Technology (MIT), and becoming a weather forecaster for the Army Air Corps (now the Air Force) operating out of Saipan, and later Okinawa.

After the war, Lorenz decided to pursue academic studies of meteorology rather than mathematics, completing his Ph.D. work at MIT in 1948 and being appointed to the MIT faculty in the mid-1950s. He became interested in the problem of forecasting the weather by using a digital computer to integrate the known equations governing the behavior of fluids like the atmosphere. At the time, a group of statisticians proposed that anything that could be forecast by integrating equations could be forecast at least as well using statistical techniques. Lorenz intuitively felt that was wrong and set out to prove it. By the early 1960s he had found a set of very simple equations that demonstrated certain properties that were then unknown in mathematics, including extreme sensitivity of forecasts to the specification of the initial state of the system. These results were published in a meteorological journal (Lorenz 1963), which later made him famous as the father of chaos theory.

Arguably, his most important contribution came in a paper published 6 years later (Lorenz 1969) in which he demonstrated, using a particular mathematical system representing turbulent flows, that the solutions could not be predicted beyond a certain definite time no matter how small one made the errors in the description of the initial state. When married with Irwin Schrodinger's uncertainty principle, this implies that there exist systems that fundamentally cannot be predicted beyond a certain time horizon.

Lorenz died in April, 2008, having made many important contributions to atmospheric science in addition to his fundamental work on chaos theory.

Loss Function

Tanujit Chakraborty and Uttam Kumar
Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Over the past few decades artificial intelligence has paved the way for automating routine labor, understanding speech and images, tackling the geosciences and remote sensing problems, supporting basic scientific research through intelligent software, etc. Majority of the tasks are performed through learning from data which is popularly known as machine learning. The generalization performance of a learning method is its prediction capability on independent test data. While assessing the performance of the learning methods, one desires to achieve two separate goals: (a) model selection – estimating the performance of different models in order to choose the best one; (b) model assessment – after selecting a final model, estimating its prediction or generalization error on a new dataset (Hastie et al. 2009). Loss function acts as a building block during this learning phase and enables the algorithm to model the data with higher accuracy. Loss function (also known as cost function or an error function) specifies a penalty for an incorrect estimate from a statistical or machine learning model. Typical loss functions might specify the penalty as a function of the difference between the estimate and the true value, or simply as a binary value depending on whether the estimate is accurate within a certain range. Any loss criterion in classification actually penalizes negative margins more heavily than positive ones as positive observations have already been correctly predicted by the model.

Introduction

Learning and improving upon past experiences is the key step in the arena of research of data science and artificial intelligence. In order to understand how a machine learning algorithm learns from data to predict an outcome, it is essential to understand the underlying concepts involved in training an algorithm. The data on which a learning algorithm is trained can be broadly classified as labeled and unlabeled data and the learning is termed as supervised learning and unsupervised learning accordingly. During the training phase, an algorithm explores the data and identifies patterns for determining good values for all the weights and the bias from labeled examples. In supervised learning, a machine learning algorithm builds a model by examining many examples and attempting to find a model that minimizes loss; this process is called empirical risk

minimization (Raschka and Mirjalili 2019). Loss functions are related to model accuracy. If the current output of the algorithm deviates too much from the expected ones, loss function would stump up a very large number. If they are pretty good, it will output a lower number. Gradually, with the help of some optimization functions, loss function learns to reduce the error in prediction (Bishop and Nasrabadi 2006). In Bayesian decision theory, loss function states how costly could be - the use of more than one feature, allowing more than two states of nature for generalization for a small notable expense, allowing actions other than classification facilitating rejection, etc. It is used to convert a probability determination into a decision (Duda et al. 2000).

What Is Loss Function?

We shall begin with a quote by François Chollet, “A way to measure whether the algorithm is doing a good job — this is necessary to determine the distance between the algorithm’s current output and its expected output. The measurement is used as a feedback signal to adjust the way the algorithm works. This adjustment step is what we call learning” (Chollet 2021).

During the training phase of any supervised learning algorithm, the data-modeler computes the error function for each individual instances by calculating the difference between the actual value and the predicted value. In the next step, the loss function is evaluated as the average error over all training data points. If the model’s prediction is perfect, the loss is zero; otherwise, the loss is greater. The goal of training a model is to find a set of weights and biases that have low loss, on average, across all examples. We shall visualize the loss for a regression problem where we wish to predict the price of an apartment in New York City. We consider two models and calculate the losses for each of them as depicted in Fig. 1. Here the predictions are represented by blue lines and the red arrows indicate the loss. Depending on the problem, the loss function may be directionally agonistic, i.e., it doesn’t matter whether the loss is positive or negative. All that matters is the magnitude. This is not a feature of all loss functions; in fact, the loss function will vary significantly based on the domain and unique context of the problem that we are applying machine learning algorithms to. In some situations, it may be much worse to guess too high than to guess too low, and the loss function we select must reflect that. The machine learning problem of classifier design is usually studied from the perspective of probability elicitation in statistical learning. This shows that the standard approach of proceeding from the specification of a loss to the minimization of conditional risk is overly restrictive. Earlier literature on loss functions is highly biased toward convex loss functions. Recently, various new loss functions have been derived in the literature which

Loss Function, Fig. 1 Plot of predicted value (blue), actual output (shaded circle) and loss for each example (red arrows)

are not convex and robust to the contamination of data with outliers, for details see (Vortmeyer-Kley et al. 2021).

Different Kind of Loss Functions

There is no “one-size-fits-all loss function” in machine learning algorithms. There are various factors that influence the choice of loss function – one of the major influential factors being the type of problem under consideration. Based on that, loss function can be broadly classified as follows:

Regression Loss Function

Regression is a supervised learning method that is used to estimate the relationship between a continuous dependent variable and a set of independent variables. In this section, we will focus on some common loss functions used for the prediction of dependent variable (Hastie et al. 2009). The mathematical expressions of these loss functions are stated using the notations where Y_i indicates the target value, $h(x_i)$ gives the predicted output, and n is the total number of examples.

Mean Absolute Error (MAE) or L1 Loss Function

L1 loss function minimizes the absolute differences between the estimated values and the existing target values. Mathematically, the mean absolute error (MAE) is given by

$$MAE = \frac{1}{n} \sum_{i=1}^n |Y_i - h(x_i)|.$$

One of the major drawbacks of MAE is that it is a scale-dependent measure hence one cannot obtain the relative size of the loss from this measure. To overcome this problem, Mean Absolute Percentage Error (MAPE) was proposed to compare forecasts of different series in different scales. Mathematically, MAPE is denoted as follows:

$$MAPE = \frac{100\%}{n} \sum_{i=1}^n \left| \frac{Y_i - h(x_i)}{Y_i} \right|.$$

Mean Squared Error (MSE) or L2 Loss Function

Mean Squared Error (MSE) is the workhorse of basic loss functions; it's easy to understand, implement, and generally works pretty well. To calculate MSE, we take the difference between model predictions and the ground truth, square it, and average it out across the whole dataset. The L2 loss function is computed as:

$$MSE = \frac{1}{n} \sum_{i=1}^n (Y_i - h(x_i))^2.$$

A special case of MSE is Root Mean Square Error (RMSE). It is computed as the square root of the MSE and is given by:

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (Y_i - h(x_i))^2}.$$

In Fig. 2 we have plotted the MAE and MSE loss values for each individual predictions in the interval $(-10, 10)$ where the actual output is assumed to be 0.

Log-Cosh Loss

Log-cosh is another loss function used in regression tasks that is smoother than L2 loss function (as evident from Fig. 3). It is the logarithm of the hyperbolic cosine of the prediction error. The mathematical formula is given by:

$$\log - \cosh = \sum_{i=1}^n \log(\cosh(h(x_i) - Y_i)).$$

Huber Loss or Smooth Mean Absolute Error

A combination of L1 & L2 loss functions accompanied with an additional parameter delta (δ) gives us the Huber loss. The shape of the loss function is influenced by this parameter (as demonstrated in Fig. 3). So, the delta parameter is fine-tuned by the algorithm. When the predicted values are far from the original, the function has the behavior of the MAE,

Loss Function, Fig. 2 Plot of MAE (left) and MSE (right) loss functions

Loss Function, Fig. 3 Plot of log-cosh (left) and Huber (right) loss functions

closed to the actual values, the function behaves like the MSE. The mathematical form of the Huber Loss is given by (Hastie et al. 2009):

$$L_{\delta}(y, h(x)) = \begin{cases} \frac{1}{2} (y - h(x))^2 & \text{for } |y - h(x)| \leq \delta, \\ \delta |y - h(x)| - \frac{1}{2} \delta^2 & \text{otherwise.} \end{cases}$$

Quantile Loss

The functions discussed so far give us a point estimate of the loss, whereas in certain real-world prediction problems, interval estimate of the loss function can significantly improve decision-making processes. Quantile loss functions turn out to be useful when we are interested in predicting an interval instead of only point predictions. Quantile-based regression aims to estimate the conditional “quantile” (of order γ) of a response variable given certain values of predictor variables. Quantile loss is an extension of MAE (when the quantile is 50th percentile, it is MAE). It is computed as follows:

$$L_{\gamma}(y, h(x)) = \sum_{i=y_i < h(x_i)} (\gamma - 1) \cdot |y_i - h(x_i)| + \sum_{i=y_i \geq h(x_i)} (\gamma) \cdot |y_i - h(x_i)|.$$

The value of the quantile to be used depends on the formulation of the problem, i.e., whether we wish to penalize overestimation or underestimation more severely. For example, a quantile loss function of $\gamma = 0.25$ gives more penalty to overestimation and tries to keep prediction values a little below median. Figure 4 exhibits the shape of the quantile loss for various values of quantiles.

Some of the observations from the regression loss functions discussed above are as follows:

- MAE is more robust to outliers, whereas MSE is a differentiable function and hence more widely used than its MAE counterpart. However, both MAE and MSE penalizes the large prediction errors.

Loss Function, Fig. 4 Plot of quantile loss function

- Huber loss function is less sensitive to outliers than the MSE as it treats error as square only inside an interval.
- The predictions are little sensitive to the value of the hyperparameter chosen in case of the model with Huber loss.
- The quantile loss gives a good estimation of the corresponding confidence levels.

Classification Loss Function

Classification is a predictive learning problem where a class label is predicted for a given set of input data. The loss functions that are commonly used to compute distances between prediction and categorical target variables in classification problems are given below (Hastie et al. 2009).

Cross Entropy

Cross-entropy compares the distance (or deviance) between predictions and the actual values. Cross entropy loss increases when the predicted value diverges from the actual. This function can be used for binary and multiclass classification problems. The cross-entropy loss is ubiquitous in modern deep neural networks. Mathematically, it is computed as follows:

Cross entropy loss

$$= \begin{cases} -(y \log(p)) - (1 - y) \log(1 - p) & \text{for } M = 2, \\ -\sum_{c=1}^M y_{o,c} \log(p_{o,c}) & \text{for } M > 2, \end{cases}$$

where M = number of classes, $\log$ = the natural logarithm, y = indicator if the class label c is the correct classification for the observation o , p = predicted probability for observation o that it belongs to class c .

There are several types of cross entropy loss functions in literature. Among them, binary cross entropy or log loss is

Loss Function, Fig. 5 Plot of cross entropy loss function

used only for binary classification problems (commonly used in logistic regression) where the target can take either of the two values 0 or 1. It measures the distance from the actual class (0 or 1) to the model's prediction, which is a probability (i.e., value in $[0-1]$). The shape of the loss function (as in Fig. 5) is convex and grows linearly for negative values (less sensitive to outliers). For any given problem, a lower log loss value indicates better prediction. Log loss function can be interpreted as the negative average of the log of the predicted probabilities. On the other hand, categorical cross entropy can be used for both binary and multiclass problems having two or more labels, the label needs to be encoded as categorical, one-hot encoding representation. Sparse categorical cross-entropy is used for both binary and multiclass problem. The number of floating-point values per feature should match the number of classes in the prediction and a single floating-point value should be present per feature for the target variable.

Logistic Loss

Logistic loss is a variant of the binary cross entropy up to a constant multiplier $1/\log(2)$. Similar to the log loss function, logistic loss is also less sensitive to outliers. It is widely used for optimizing LogitBoost algorithm (Friedman et al. 2000).

Exponential Loss

The exponential loss is a convex function and grows exponentially for negative values which makes it more sensitive to outliers. The exponential loss, widely used in optimizing AdaBoost algorithm, is defined as follows:

$$\text{Exponential loss} = \frac{1}{N} \sum_{i=1}^N e^{-h(x_i) * y_i},$$

where N is the number of examples, $h(x_i)$ is the prediction for i^{th} example, and y_i is the target for the i^{th} example.

Hinge Loss

The hinge loss is used for “maximum-margin” classification, most notably for support vector machines (SVMs) (Rosasco et al. 2004). The goal is to make different penalties at the point that are not correctly predicted or are too close to the hyper-plane. Its mathematical formula is:

$$\text{Hinge loss} = \max(0, 1 - y * h(x)),$$

y is the target vector and $h(x)$ is the predicted vector. Hinge loss function can be used for both binary classification and multi-class classification.

Kullback-Leibler Divergence Loss

Kullback–Leibler divergence, D_{KL} (also called relative entropy), measures how one probability distribution is different from a reference probability distribution. Usually, P represents the data and the predictions are encoded as Q . The Kullback–Leibler divergence is interpreted as the information gain achieved if P would be used instead of Q which is currently used. The relative entropy from Q to P is denoted by $D_{KL}(P||Q)$ and is evaluated as

$$D_{KL}(P||Q) = \sum_{x \in \mathcal{X}} P(x) \log \left(\frac{P(x)}{Q(x)} \right),$$

where P and Q are discrete probability distributions on the probability space $\mathcal{X}$. For P and Q being the distributions of continuous random variables $D_{KL}(P||Q)$ is defined as

$$D_{KL}(P||Q) = \int_{-\infty}^{\infty} p(x) \log \left(\frac{p(x)}{q(x)} \right) dx,$$

where p and q are the probability densities of P and Q , respectively (MacKay and Mac Kay 2003). Kullback-Leibler divergence is not symmetric and does not follow triangle inequality.

Loss Function in Geoscience

Geoscience is a field of great societal relevance that require solutions to several urgent problems such as predicting impact of climate change, measuring air pollution, predicting increased risks to infrastructures by disasters, modeling future availability and consumption of water, food, and mineral resources, and identifying factors responsible for natural calamities. As the deluge of big data continues to impact practically every commercial and scientific domain, geoscience has also witnessed a major revolution from being a data-poor field to a data-rich field. This has been possible with the advent of better sensing technologies, improvements in computational resources, and internet-based democratization of

data. The growing availability of geoscience big data offers immense potential for machine learning practitioners to apply state-of-the-art methodologies to model this data (Samui 2008); (Toms et al. 2020). The popular types of algorithms that are used in these applications include artificial neural network, support vector machine, self-organizing map, decision trees, ensemble methods such as random forest, neuro fuzzy, multivariate adaptive regression splines, etc. These models use various loss functions in their training phase, however, the most commonly used loss functions in geoscience applications incorporates cross-entropy loss function and Huber loss function due to higher overall accuracy and better learning efficiency.

Summary

Loss functions provide more than just a static representation of how the model is performing – they are how the algorithms fit data in the first place. Most machine learning algorithms use some sort of loss function in the process of optimization or finding the best parameters (weights) for the data. Importantly, the choice of the loss function is directly related to the formulation of the problem. As such, absolute loss in regression is same as binomial deviance in classification; it increases linearly for extreme margins. Exponential loss is more undesirable than squared-error-loss. When considering robustness in spatial data analysis, squared error loss for regression and exponential loss for classification are not idle. However, they both lead to sophisticated boosting method in forward stagewise additive modeling setting. One must understand that none of the loss functions can be treated as universal, however, choosing a loss function is a difficult proposition and depends on the choice of machine learning model for the problem in hand. We can think of selecting the algorithm as a choice about framing of the prediction problem, and the choice of the loss function as the way to calculate the error for a given framing of the problem. A future scope of research on the area of loss function in geoscience would be to work with Wasserstein loss which has got much attention in machine learning domain for the last decade.

Data and Code

Machine Learning

Feifei Pan

Rensselaer Polytechnic Institute, Troy, NY, USA

Definition

Machine learning is the science which allows humans to design algorithms and teach computers to learn patterns from vast amounts of data and use the patterns to automatically make decisions or predictions. In this process, data can be and not limited to the following types: numeric values, text, graph, photos, audio, and more. Machine learning is considered as a subset of artificial intelligence. It is closely related to computational statistics, data science and data mining and frequently applied to other research domains such as natural language processing, computer vision, robotics, bioinformatics, and so forth.

Introduction

Machine learning automates computers to make decisions or predictions without being explicitly programmed so. With the exponential growth of data, machine learning has become a crucial component behind many great inventions and services in the past decades. For instance, machine learning enables the accurate recommendation systems for online shopping websites such as Amazon and eBay, the effective search engines such as Google, Baidu, and Bing, the convenient voice assistant systems such as Siri and Alexa.

Machine learning has attracted considerable attention since the past century. As early as 1950, Alan Turing raised the questions, “Can machines think?”, in his paper *Computing machinery and intelligence* (Turing 2009). Later in 1959, the term machine learning was first introduced by Arthur

Samuel in his paper on computer gaming *Some studies in machine learning using the game of checkers* (Samuel 1959). Nilsson pioneered the research in machine learning with the book *Learning Machines* in the 1960s, which focused on pattern classification in the discriminant machine systems. Since then, substantial efforts have been put into machine learning research. With the publication of Hinton’s highly-cited paper *Learning representations by back-propagating errors* (Rumelhart et al. 1988) in late 1980s, machine learning research welcomed the era of deep learning.

In general, a learning process in machine learning can be described as the following: (1) the model input is denoted as x ; (2) the target, can be either a decision or a prediction, is denoted as Y ; (3) a dataset D is also provided, where $D = \{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\}$, note that y is not always necessary for input data of semi-supervised and unsupervised learning models. The goal of a learning process is to learn a function $g: X \rightarrow Y$ that closely approximates the true relation between inputs and outputs $f: X \rightarrow Y$ (Abu-Mostafa et al. 2012). The exact target function $f: X \rightarrow Y$ usually cannot be learned due to the limitation of data. When encountering unseen data x_i , a Y_i can be automatically generated by computers using the learned function $g: X \rightarrow Y$. In most cases, the function $g: X \rightarrow Y$ is chosen from a set of hypothesis functions based on the characteristics of the data and the properties of the learning tasks.

Type of Learning

There are various types of learning designed for different types of input/output data and learning problems. The learning types can be roughly categorized into four major classes: supervised learning, unsupervised learning, semi-supervised learning, and reinforcement learning. Some other learning types include self-learning, feature learning, association rule learning, etc.

Supervised, Unsupervised, and Semi-Supervised Learning

Supervised learning is designed for labeled data, which means the input data are data pairs (x_i, y_i) with both input x_i and ground truth output y_i (usually manually labeled). The input data for a supervised model is split into two non-overlapping datasets: training data and testing data. A supervised learning model is built on training data pairs to learn the function $g: X \rightarrow Y$ discussed in section “Introduction.” The function g is later applied to the unseen testing data for evaluation. Supervised learning includes classification and regression algorithms, such as k -nearest neighbors, support vector machines, logistic regression, naive Bayes, decision trees, Stochastic Gradient Descent, etc. Active learning and online learning are two of the main variations of supervised learning (Abu-Mostafa et al. 2012).

In contrast to supervised learning, unsupervised learning (Hinton et al. 1999) involves unlabeled data. Hence, the input data for unsupervised models only contains x , and the goal of unsupervised learning is to directly learn patterns or structures among data. The primary approach of unsupervised learning is cluster analysis, an algorithm that groups unlabeled data into N clusters based on the underlying similarities. K-means, hierarchical clustering, mixture models, and density-based spatial clustering of applications with noise (DBSCAN) are well-known algorithms for clustering. The main advantage of unsupervised learning is that it requires a minimum amount of supervision and human efforts, especially for data annotation.

Semi-supervised learning, similar to its literal meaning, is a hybrid of supervised and unsupervised learning. The model input consists of a small amount of labeled data and a sizable amount of unlabeled data. While unsupervised learning tends to produce lower accuracy, semi-supervised learning introduces a small amount of labeled data for model tuning, which considerably enhances the model performance without significantly increase the annotation expense.

Reinforcement Learning

Reinforcement learning is also built on unlabeled data but works differently from unsupervised learning. It is most similar to how humans and animals learn basic skills. Imagining a puppy is given a treat every time he/she sits after the command “sit” and is given nothing if he/she does something else. With several repetitions, the puppy gradually learns the correct action to take after the “sit” command under this reward mechanism. In reinforcement learning, the computer is trained similarly: for each input training sample, the outcome is measured accordingly, and the final goal is to maximize the reward for all samples. Reinforcement learning is particularly useful in game theory, control theory, and operations research.

Learning Models

A standard machine learning process involves model building. Commonly seen models include simple models such as linear regression, support vector machine, decision tree, k -nearest neighbors, and more complex models such as neural networks.

Linear Models

The general idea of linear models is to learn a set of weights, also called coefficients, denoted as $w = (w_1, w_2, w_3, \dots, w_n)$ for every feature x_i of the input data X . The predicted value $\hat{y}$ is the linear combination of w and X , where:

$$\hat{y} = w_0 + w_1x_1 + w_2x_2 + \dots + w_nx_n$$

with w_0 denotes a constant.

The basic linear regression model aims to minimize the sum of squared errors between the predicted values and the ground truth. Mathematically speaking, the linear regression model learns a set of coefficients to minimize the cost function, denotes as:

$$\sum_{i=1}^n (y_i - \hat{y}_i)^2 = \sum_{i=1}^n \left(y_i - \sum_{j=0}^k x_{ij}w_j \right)^2$$

Lasso (least absolute shrinkage and selection operator) regression (Tibshirani 1996) is a variation from the basic linear model. It aims to minimize the sum of squared errors with a tuning parameter, also known as the $L1$ regulation. The cost function of lasso regression is:

$$\sum_{i=1}^n (y_i - \hat{y}_i)^2 = \sum_{i=1}^n \left(y_i - \sum_{j=0}^k x_{ij}w_j \right)^2 + \lambda \sum_{j=0}^k |w_j|$$

where λ is a constant and $\sum_{j=0}^k |w_j|$ represents the $L1$ norm. With the regulation, lasso regression automatically performs feature selection and reduces overfitting.

Other widely used linear models include logistic regression, multi-task lasso, elastic-net, Bayesian regression and more.

Support Vector Machine

The Support Vector Machine(SVM) model (Cortes and Vapnik 1995) is a set of supervised algorithms that construct multiple high-dimensional hyperplanes in vector spaces for regression and classification tasks. The SVM model is very effective for high-dimensional data, especially when the datasets are relatively small. It is also very flexible: SVM’s

decision functions vary with the selection of the kernel functions. Linear, polynomial, sigmoid and Radial Basis Function (RBF) are the frequently used kernel functions for SVM models. Customized kernel functions are also possible for SVM models.

Decision Tree

A decision tree model produces a flowchart-like, tree-structured hierarchy. Each branch represents a condition or a feature, and each bottom layer leaf node represents a class or a label. Decision tree learning is widely used in classification (Classification tree) and regression (Regression tree) tasks. To enhance the accuracy of decision tree learning, Ho Tin-kam proposed the random forest, or the random decision forests model, in her work *Random decision forests* in 1995 (Ho 1995). Random forest is an ensemble learning method that constructing multiple decision trees and outputting based on the predictions of all decision trees. Random forest model increases the accuracy of the decision tree algorithm and reduces overfitting.

Neural Networks

Neural networks, the foundation of deep learning, are learning models that designed to replicate the mechanism of human brains. A typical neural network model has an input layer, one or multiple connected, hidden layers and an output layer. Signals are transmitted through the neurons in each layer and the hidden layers can be organized and connected in different fashion, as shown in Fig. 1. Neural networks can be simple as multi-layer perceptrons and can also be complicated as RNN, CNN, and Long/Short Term Memory (LSTM) models. Neural network models can be used in supervised, unsupervised, semi-supervised, and reinforcement learning. It has a high requirement for computational power but is famous for its portability, robustness, and high accuracy.

Issues and Limitations

Overfitting is one of the most common issues for machine learning models. It occurs when a model only focuses on perfectly fitting the training data while loses generality and

Machine Learning, Fig. 1 Diagrams of three neural network architectures: Recursive Neural Network (RvNN), Recurrent Neural Networks (RNNs), and Convolutional Neural Networks (CNNs). It is the Fig. 1 in

A Survey on Deep Learning: Algorithms, Techniques, and Applications (Pouyanfar et al. 2018)

causes low performance on unseen validation data. Overfitting is very likely to increase the computational cost and lower the portability of the models. However, overfitting can be avoided through properly-designed cross-validation.

Machine learning models highly rely on the quality of data. Lack of data, biased data, and inaccessible data are some of the significant issues that fail machine learning models. Training with low-quality data may cause algorithmic bias and requires additional human supervision and remedy. Recently, Xin et al. proposed the idea of Human-in-the-Loop Machine Learning in Xin et al. (2018), which integrates human efforts into the traditional machine learning process and achieves impressive results on typical iterative workflows.

Computers, as one of the essential components in learning processes, can also become a barrier to the development of machine learning. Deep learning was first emerged in the early twentieth century but did not fully blossom until the late 1990s when the graphics processing units (GPU) were developed. The quality of computer hardware also largely contributes to the success of learning.

Summary and Conclusions

Machine learning offers a solution for accurate and quick data analysis and knowledge discovery in this big data era and enables the advancements in artificial intelligence. Despite the minor drawbacks mentioned in section “[Issues and Limitations](#),” machine learning now tackles various type of data under different problem settings and has been successfully applied to solve data problems in diverse research domains.

Biography

Benoit Mandelbrot has contributed much to several branches of science, often in pioneering ways, by seeing what others could not see. I will describe two of his contributions to turbulence (but omit other topics such as vortical boundaries and the R/S analysis of hydrological data). Chapter ten of his book (Mandelbrot 1982), which he regarded as “[a plea] for a more geometric approach to turbulence and for the use of fractals,” discusses his thoughts at the time; it is fair to say,

however, that those views have been superseded in significant ways.

One of them was his speculation, on the basis of a free-hand sketch prepared by S. Corrsin (1959), that the interface bounding a dye mixed by homogeneous turbulence is a fractal. His ideas on this topic, expressed in his 1982 book (also its 1977 predecessor), were free-wheeling yet remarkable because, at that time, there was no real evidence to back up his speculations. It took me and my colleagues many years of diligent work to bring realism to them; I cite two examples that are almost three decades apart (Sreenivasan 1991; Iyer et al. 2020). A comparison of Corrsin's schematic (see p. 54 of Benoit's 1982 book) was accomplished by actual direct numerical simulation, finally, in Sreenivasan and Schumacher (2010). This comparison reveals both the fertility of past imagination and its limitations.

The second contribution described here stemmed from the fact, well-known at the time, that turbulent energy dissipation is intermittent in amplitude, in both space and time. Benoit knew that a single fractal dimension would not suffice for describing this property, and developed further ideas (Mandelbrot 1974): while geometric objects such as interfaces can be characterized meaningfully by a single fractal dimension, others such as energy dissipation require a multitude of dimensions. Benoit's ideas were not yet sharp and, to his later chagrin, he did not use the term "multifractal" until after it was first used by Frisch and Parisi (1985); the characterization of multifractal measures (without using the word multifractal) was the work of Halsey et al. (1986). Later, Benoit connected these developments to his earlier ideas of 1974 and gave a beautiful probabilistic interpretation of multifractals, which led him to devise concepts such as negative and latent dimensions (see Chhabra and Sreenivasan 1991). Meneveau and I (1987, 1991) – see also Sreenivasan (1991) – connected these concepts meaningfully to turbulence, made measurements of the multifractal spectrum for energy dissipation and other such quantities, and developed and measured joint multifractal measures.

Benoit was my colleague at Yale for many years. My students and I benefitted greatly from discussions with him, for which I am grateful. His enthusiasm for our work was remarkably uplifting. He was well aware of being described as the "father of fractals," and he once told me that fractals as a subject wouldn't exist without him; he is probably right. His most memorable lines are recorded in his magnum opus, the 1982 book: "Clouds are not spheres, mountains are not cones, coastlines are not circles, and bark is not smooth, nor does lightning travel in a straight line." Toward the end of his career, Benoit tried to recast his legacy as having brought attention to the overarching theme of "roughness" as an important fact of Nature, whereas much of the rest of science was focused on smoothness.

All in all, Benoit was a unique scientist who ventured into several areas, some of which went beyond science, and originated key concepts in each of them. He has an assured place in the annals of Science.

Markov Chain Monte Carlo

Swathi Padmanabhan and Uma Ranjan

Indian Institute of Science, Bangalore, Karnataka, India

Definition

Probabilistic inference is a way to derive the probability of a set of random variables, and it can take a set of value/values. Markov chain Monte Carlo (MCMC) is a stochastic process that aims to get the inference through efficient sampling means. Markov chain Monte Carlo (MCMC) is a class of methods that combines the Markov chains to Monte Carlo sampling for efficient sampling. This method helps construct the "most likely" distribution that gets us closer to the actual or expected distribution. The Bayesian approach helps quantify the uncertainty and thus gives a method to sample the inference. Various distributions of physical parameters can be studied with the help of this MCMC as the use of posterior distribution maximizes the expectation of the desired

parameter. Many extensive applications can be found for MCMC from analyzing rock physics to understand the weak points of rock to developing efficient deep learning algorithms to better analyze various phenomena. Some include modelling distributions of geochronological age data and inference of sea-level and sediment supply histories from 2D stratigraphic cross-sections (Gallagher et al. 2009) and so on.

Introduction

In the computation of Bayesian inverse problems, an important step is that of sampling the posterior distribution. The parameters of interest correspond to the properties of the posterior distribution. The direct calculation of this parameter is computationally intractable. Hence, the posterior probability must be approximated by other means (Svensén and Bishop 2007). Typically, the desired calculations are done as a sum of a discrete distribution of many random variables or integral of a continuous distribution of many variables and is difficult to calculate. This problem exists in both schools of probability (Bayesian and Frequentist); it is more prevalent with Bayesian probability and integrating over a posterior distribution for a model.

One common solution to extract inference is by Monte Carlo sampling. This method draws independent samples from the probability distribution, and then repeat this process many times to approximate the desired physical quantity. Markov chain is a systematic method of predicting the probability distribution of the future or next state based on the current state. Monte Carlo samples the random variables independent from each other directly from the desired probability density function but fails at higher dimensions. Markov chain Monte Carlo (MCMC) combines both these methods and allows random sampling of high-dimensional probability distributions that takes into account the probabilistic dependence (transition probability) between samples by constructing a Markov chain that comprise the Monte Carlo sample (Gelman and Lopes 2006).

Historically speaking, Monte Carlo methods have existed since World War II times. The first MCMC algorithm, now Metropolis algorithm, was published in 1953. But more practical aspects and integration with statistics took when the work of Hastings came in the 1970s. The development of Monte Carlo methods during the 1940s coincided with the development of the first computer, ENIAC. Von Neuman set the computation of the Monte Carlo method was set up by Von Neuman for analyzing thermonuclear and fission problems in 1947. Fermi invented the version without computers in the 1930s, but it did not gain any recognition. The Metropolis algorithm (first MCMC algorithm) was developed using MANIAC computer under the guidance of Nicholas Metropolis in the early 1950s. From the 1990s to the present, the

evolution involves these algorithms taking in various advances like the Gibbs sampling, perfect sampling, regeneration, and central limit theorem for convergence and so on. Over time, the algorithms have evolved and significantly advanced along with the growth of computation; these techniques have influenced many aspects and applications (Robert and Casella 2011).

Monte Carlo Sampling

Monte Carlo estimates the physical quantity desired as the expectation of random variable averaged over a large number of samples for a desired density function. MC methods are used to solve problems that are stochastic in nature (particle transport, telecommunication systems, population studies based on the statistical nature of survival and reproduction) and that are deterministic (solving integrals, complex linear algebra equations, solving complex partial differential equation (PDE)). The main advantages of using Monte Carlo sampling are to:

1. Estimate density by collecting samples to approximate the distribution of a target function.
2. Approximate a parameter (physical quantity), like the mean or variance of a distribution.
3. Optimize a function by locating a sample that maximizes or minimizes the target function or the desired distribution.
4. Estimate more than one physical quantities simultaneously by using more than one random variables.

The random numbers are generally considered to follow a uniform distribution or any probability function desired. The random number generated are independent, thus having no correlation between each sample generated. Sometimes, pseudorandom sequences are used for rerunning the simulations where the pseudorandom sequences involves a known deterministic sequence to sample the random the samples from the probability density function of the physical quantity that needs to be predicted. This method is generally known as inverse distribution method and this is used for Monte Carlo simulations in optical imaging methods (Wang and Wu 2012). The sampling process in Monte Carlo can be explained as follows (Goodfellow et al. 2016).

Consider the expectation defined over an integral of a probability density (or distribution) over a random variable x :

$$q = \int f(x)p(x) = E[f(x)] \quad (1)$$

If Eq. 1 is the integral to estimate the quantity q , then q can be approximated by drawing “ n ” number of samples and then by averaging it as (Goodfellow et al. 2016):

$$\hat{q}_n = \frac{1}{n} \sum_{i=1}^n f(x^i) \quad (2)$$

$\hat{q}_n$ is the average of n samples for a quantity, q . The **law of large numbers** in statistics states that if the samples x^i are i.i.d, then the average value, $\hat{q}_n$, will definitely converge to the expected values of the random variable, provided the variance is bounded by:

$$\text{Var}[\hat{q}_n] = \frac{\text{Var}[f(x)]}{n} \quad (3)$$

$\text{Var}[\hat{q}_n]$ is the variance of $\hat{q}_n$, $f(x)$ is the distribution of the samples and $\text{Var}[f(x)]$ is the variance of the $f(x)$. By **central limit theorem**, we can say that the distribution of $\hat{q}_n$ to a normal distribution has a finite mean and variance. In this case, the mean will be q and variance as in Eq. 3. Hence, from these outcomes, accurate estimations of $\hat{q}_n$ can be done from the corresponding cumulative distribution of the normal density function. The graphical illustration (Wang and Wu 2012) of sampling from a distribution described in Fig. 1 will give a better knowledge of generating the pseudorandom random numbers when we have specific probability density function as goal.

Drawbacks

The main drawbacks of Monte Carlo Sampling are:

- MC sampling fails at high dimensions because the volume of the sample space increases exponentially with the number of parameters (dimensions).
- MC samples each of the random sample from the desired base probability density function and each of them are independent and is drawn independently as well. This increases the complexity of the model.

Markov Chain Monte Carlo (MCMC)

The framework for MCMC provides a general approach for generating Monte Carlo samples from the posterior distribution, in cases where we cannot efficiently sample from the posterior directly. We get the posterior distributions in Bayesian inference (Ravenzwaaij et al. 2018). In MCMC, we construct an iterative process that gradually samples from distributions that are closer and closer to the posterior. The challenge is to decide how many iterations we should perform before we can collect a sample as being (almost) generated from the posterior (Koller and Friedman 2009).

Markov Chain Monte Carlo,

Fig. 1 Example illustration of sampling a random variable x from a desired probability density function $p(x)$ based on a random number ξ generated from a uniform distribution in interval $[a, b]$. The graph also shows the mapping with the cumulative functions of the same.

Markov Chains

Markov Chain is a special type of stochastic process, which deals with characterization of sequences of random variables. It focuses on the dynamic and limiting behaviors of a sequence (Koller and Friedman, 2009). It can also be defined as a *random walk* where the next state or move is only dependent upon the current state and the randomly chosen move.

Also, the sampling can be explained using chain dynamics as follows. Consider a random sequence of states $x^0, x^1, x^2, \dots, x_k$ with weights $w_1, w_2, w_3, \dots, w_k$ is shown in Fig. 2. Let the state of the process at step “ k ” be viewed for a random variable X^k . We assume that the initial state X^0 is distributed according to some initial state distribution $P^0(X^0)$. The definition of subsequent states of P are $P^1(X^1), P^2(X^2), P^3(X^3)$.

$$P^{(k+1)}(X^{(k+1)} = x') = \sum_{x \in \text{Val}(X)} P^{(k)}(X^{(k)} = x) T(x \rightarrow x') \quad (4)$$

where the state transition from x to x' at $k+1$ is nothing but the sum of all the possible states of x at step “ k .” Markov chains provides good insight to random walk models, but as a standalone model, it is inefficient to reach inferences.

Designing MCMC

For implementing a Markov chain Monte Carlo, there are certain conditions of the process to be understood. Firstly, the Markov chain process is considered to be stationary, or it is sampled until it comes to the stationary state. If we arrive at the stationary distribution (invariant distribution) of Markov chain, then it continues to remain in that state for all the future samples of Monte Carlo. The condition for a Markov chain to be stationary is given by definition as (Koller and Friedman 2009):

$$\pi(X = x') = \sum_{x \in \text{Val}(X)} \pi(X = x) T(x \rightarrow x') \quad (5)$$

where the T denotes the transition probability and π denotes the probability of the states of each sample X . An

Markov Chain Monte Carlo, Fig. 2 A very simple Markov chain representing states $x_0, x_1, x_2, \dots, x_k$ with weights $w_1, w_2, w_3, \dots, w_k$

important property of a transition model of Markov chain is that, for a stationary distribution, the transition model T can be viewed as a matrix A (also known as adjacency matrix). The stationary Markov distribution is then an eigen vector of the matrix A corresponding to the eigen value 1.

The representation of a Markov chain sampling using adjacency matrix, A in linear algebra context and π as probability states:

$$\pi A = \pi \quad (6)$$

where this relation shows the eigen vector relationship between the states and π is the target distribution.

In MCMC, the samples are drawn from the probability distribution by building a Markov Chain, and the next sample is drawn from the probability distribution that dependent upon the last sample that was drawn. After an initial number of samples, the distribution will settle or converge to become stationary (equilibrium) that will help estimate the physical quantity desired. Hence, the introduction of correlation between the sampling of variables in Monte Carlo will enable efficient estimation of the density or quantity rather than wandering over a domain.

Markov Chain Monte Carlo Algorithms

Various algorithms exist for MCMC. The two commonly used for MCMC are:

- The Gibbs sampling algorithm
- Metropolis-Hastings algorithm

The idea of MCMC is that the sequences are constructed such that, although the first sample may be generated from the prior, subsequent samples are generated from distributions that conclusively gets closer and closer to the desired succeeding values for samples (Koller and Friedman 2009).

The initial samples are important for MCMC as it is during these samples, the distributions are observed to know whether it is converging or not. From the initial point, the samples undergo a *warm-up* phase where the samples are being chained to the Markov process to reach useful values. Generally, some prior samples are eliminated or discarded from the initial phase, once useful values are attained. This is referred to as *burning-in* of Markov process that marks entry to the stationary distribution of Markov chain (Murphy 2019).

For constructing a Markov chain, the detailed balance condition is necessary.

The detailed balance condition for a finite state Markov chain is reversible if there exists a unique distribution p for all states of x :

$$\pi(\mathbf{x})T(\mathbf{x} \rightarrow \mathbf{x}') = \pi(\mathbf{x}')T(\mathbf{x}' \rightarrow \mathbf{x}) \quad (7)$$

Equation 7 asserts that the probability of a transition from $\mathbf{x}$ to $\mathbf{x}'$ is the same as the probability of a transition for $\mathbf{x}'$ to $\mathbf{x}$, which implies that a random transition from state $\mathbf{x}$ to $\mathbf{x}'$ is **reversible** and the $\mathbf{p}(\mathbf{x})$ forms a **stationary distribution** to the transition probability T (Koller and Friedman 2009).

Gibbs Sampling

Gibbs sampling is a technique used when we have to consider more than one dimensions. The density functions may also be multivariate distributions. The probability of the next state is calculated from the conditional probability of the prior state. Therefore, the new states or samples are conditioned over all the values of the entire distribution (Murphy 2019).

The conditional sampling method is easy and accurate when the dimensions are low and more difficult as dimensions increase. Gibbs sampling is an easy to implement model. The samples are acquired from the posterior distribution $P(Q|E = e)$ where “e” is the observations, $Q = X - E$. The states in the Markov chain will be defined from $\mathbf{x}$ to $\mathbf{x} - E$. Then, transition states are defined so as to converge to a stationary distribution $\pi(Q)$. For arriving at this condition, let the states in the Markov chain be (x_{-i}, x_i) . Transition probability of the upcoming states are given as:

$$\begin{aligned} T_i(x_{-i}, x_i) &\rightarrow (x_{-i}, x'_i) \\ T_i(x_{-i}, x_i) &= P(x'_i | x_{-i}) \end{aligned} \quad (8)$$

From Eq. 9, it can be understood that the transition probability for Gibbs sampling depends only on the remaining states x_{-i} for a posterior distribution $P_N(X|e)$ for a set of N factors. This shows that $P_N(X|e)$ is stationary for the process considered (Koller and Friedman 2009).

Metropolis-Hastings

Metropolis-Hastings was initially published in 1970, which was a paper that generalized the Metropolis algorithm and to overcome the dimensionality drawback of the MC methods. In this algorithm, the stationary distribution needed is acquired using the detailed balance condition in Eq. 7. with a particular stationary distribution. The Metropolis-Hastings algorithm requires a *proposal distribution* as we cannot sample directly from the required distribution. It uses the concept of acceptance probability to decide is the proposed state can be accepted or rejected. If we denote the *acceptance probability* as $A(\mathbf{x} \rightarrow \mathbf{x}')$, which gives the probability of the state, $\mathbf{x}'$ getting accepted over the proposal distribution τ^q defines the

Markov Chain Monte Carlo, Fig. 3 Illustration of acceptance probability using an example distribution $p(x)$ on the proposed states. If the $\mathbf{x}'$ is towards the denser part of distribution (green point), then the state is accepted else it might or not be accepted as in the state denoted by blue point

transition model for a given state space. The random states are generated using the defined proposal distribution.

When two successive states are generated, the state can be either accepted or rejected based on their acceptance probabilities. For example, if the new state $\mathbf{x}'$ is found to satisfy the desired density function $\mathbf{p}(\mathbf{x})$ and the prior state is $\mathbf{x}$, the chance of acceptance of $\mathbf{x}'$ as the next state is higher if the state is lying closer to the higher density as in Fig. 3. This will lead to the successive states to be closer to the probability values populated around that region. Suppose if the next state is farther away as in right hand side of the distribution in Fig. 3, then it may or may not get accepted. The acceptance here depends on the distance between the current state and the proposed state.

Therefore, the condition for acceptance can be defined based on the detailed balance as:

$$\pi(\mathbf{x})T(\mathbf{x} \rightarrow \mathbf{x}')\tau^q(\mathbf{x} \rightarrow \mathbf{x}') = \pi(\mathbf{x}')T(\mathbf{x}' \rightarrow \mathbf{x})\tau^q(\mathbf{x}' \rightarrow \mathbf{x}) \forall \mathbf{x} \neq \mathbf{x}' \quad (9)$$

Then, the acceptance probability can be defined for a stationary distribution as:

$$A(\mathbf{x} \rightarrow \mathbf{x}') = \min\left(1, \frac{\pi(\mathbf{x}')\tau^q(\mathbf{x}' \rightarrow \mathbf{x})}{\pi(\mathbf{x})\tau^q(\mathbf{x} \rightarrow \mathbf{x}')}\right) \quad (10)$$

Or in other words, using conditional probability, τ^q can be denoted as a function, say V , and then

$$A(\mathbf{x} \rightarrow \mathbf{x}') = \min\left(1, \frac{p(\mathbf{x}')V(\mathbf{x}|\mathbf{x}')}{p(\mathbf{x})V(\mathbf{x}'|\mathbf{x})}\right) \quad (11)$$

If the condition for Eqs. 9 and 10 is satisfied, then the process has reached stationary state. Gibbs Sampling method is a special case of the Metropolis-Hastings method. There are cases when it becomes difficult to use the Metropolis-Hastings algorithms as result of nonlinearity in the models. In applications, Metropolis-Hastings is used in conjunction with a Gibbs sampler, but when nonlinearity in model arises, it becomes difficult to sample from the full conditional distributions. In those cases, some resampling techniques like rejection method is employed in the Metropolis-Hastings algorithm (Gamerman and Lopes 2006) especially in the context of nonlinear and non-normal models.

Summary and Conclusions

In short, Markov chain Monte Carlo (MCMC) is a method for efficiently sampling the random variables for accurate or exact estimation of the parameters necessary. Monte Carlo sampling alone cannot provide very good estimations as it fails at higher dimensions particularly. The beauty of extracting inference from Bayesian statistics is what forms the basis for MCMC. It focusses on generating samples from a posterior distribution using a reversible Markov chain that will have its converging or equilibrium distribution as the posterior distribution. The dependency created due to integration of Markov chains will ensure fast convergence to the true or exact solution while combined with Monte Carlo. The conditions for a good MCMC can be defined with the help of transition probability and the stationary condition for Markov chain. The two common algorithms for MCMC are the Gibbs sampling and the Metropolis-Hastings algorithms. Metropolis-Hastings is a more general and commonly used algorithm, while Gibbs sampling can be considered as a special case of Metropolis-Hastings. MCMC based on Metropolis-Hastings is used more because of its flexibility over other algorithms. Gibbs algorithm is more often used when the next step is the conditional probability distribution as the *proposal distribution*. There are generalized algorithms when the *proposal distributions* are symmetric in nature like the Gaussian (Murphy 2019). For efficient convergence of the models, we can design the algorithms that has altered Markov chain sequences or that alter the samples generated or the transition kernels based on the complexity of the process under study (Gamerman and Lopes 2006). Different strategies can be adopted based on the requirement of the desired target distribution.

MCMC in Geosciences: Various geophysical problems involve inverse problems wherein an input parameter and an output solution are obtained via inversion of an operator. This is commonly used in seismological models and resolution analysis and model optimization (Gallagher et al. 2009), for example, finding randomly searching earth's consistent model with seismological model. MCMC provides improved reliability in GIS systems. Generally, GIS problems are ill-posed and solved linearly. Solving nonlinear cases involve non-Gaussian changes and requirement of a posterior distribution. Since complexity involved is high, MCMC improves the prediction and reliability for the nonlinear cases. SAR (synthetic aperture radar) land applications acquires images that are RAW images composed of complex data. The speckles contained can be removed by Markovian random field grouping and the method involves estimating iteratively estimation of parameter, and the conditional posterior distribution of each pixel is updated at every step of the algorithm, with only dependent on its neighboring pixels.

Definition

Consider a system, which can be described at any point of time t using a *state variable* X_t . This state variable may be a D -dimensional vector (where D may be 1 or higher), defined on a space X called the *state space*, and each individual value in the state space is called a *state*. This space can be either discrete or continuous, depending on the nature of the system. Time may be considered to be *discrete*. *System dynamics* refers to the process by which the state of the system changes over time, so that we have a sequence of states $\{X_1, X_2, \dots, X_{t-1}, X_t, X_{t+1}, \dots\}$. The changes of state from one time-point to the next are known as *state transitions*. If the state space is discrete and finite, we can look upon a Markov chain as a finite-state machine which shifts between the different states.

Suppose, these state variables are *random variables*, i.e., their values are assigned according to probability distributions. We describe such a system as a *Markov chain* if the state transition from X_{t-1} to X_t is governed by a probability distribution that depends only on X_{t-1} , but not any previous state or any other external information, for any t . This is known as the *Markov property*. In other words

$$p(X_t | X_{t-1}, X_{t-2}, \dots, X_1) = p(X_t | X_{t-1}) \quad (1)$$

The conditional distribution $p(X_t | X_{t-1})$ satisfies the following relation: $\text{prob}(X_t = b | X_{t-1} = a) = T_t(a, b)$ where a and b are two states and T_t is any function specific to time t that defines a probability distribution for X_t with respect to b , i.e., $T_t(a, b) \geq 0 \forall a, b$, and $\sum_{b \in X} T_t(a, b) = 1$ (if χ is discrete), or $\int_X T_t(a, b) db = 1$ (if χ is continuous). If the state space is discrete and countable, T may be looked upon as a *state transition table*, where each row denotes a possible value of the current state, each column denotes a possible value of the next state, and the corresponding entry indicates the probability of such a state transition. An example of such a Markov chain is given in Fig. 1.

We can define various properties of Markov chains using *marginal distributions* of individual state variables, i.e., $P(X_t)$ for any t , or their *joint distributions*, i.e., $P(X_{t1}, X_{t2}, \dots, X_{tn})$, n is any integer and $(t1, t2, \dots, tn)$ are arbitrary time-points. A Markov chain is said to be *stationary* or *homogeneous* if the following holds

Markov Chains: Addition, Fig. 1 A three-state discrete Markov chain showing the state transition table

$$P(X_{t1}, X_{t2}, \dots, X_{tn}) = P(X_{t1+k}, X_{t2+k}, \dots, X_{tn+k}) \forall n, k \quad (2)$$

In a homogeneous Markov chain, T_t is independent of t . Further, by setting $n = 1$, it follows that the marginal distributions of all state variables of a stationary Markov chain are identical, and this distribution is called the *stationary distribution* of the Markov chain, denoted by π . This basically represents the probability distribution over the state space that the state variable can take at any time. In case of discrete state spaces, where T is the state transition matrix, it can be shown that $\pi T = \pi$.

Introduction

Markov chains are widely used in various domains of science and engineering to represent stochastic processes. They are specifically useful in applications where there is a system whose state is continuously evolving, but the evolution has a randomness associated with it. Typically, the system state cannot be directly measured. However, there are measurable quantities that are functions of the system state, and these functions may be either deterministic or stochastic. Markov chains are often used to model the system state in such situations. The main reason for choosing them are as follows: (i) They can take care of the stochasticity, and (ii) the Markov assumption is simplifying and hence computationally tractable. In most cases, the task is to solve the *inverse problem*, i.e., estimate the system state based on the observations, even though it is really the system state which produces the observations. A good example is in atmospheric sciences, where the state of the atmosphere cannot be measured directly, but other dependent variables such as temperature, precipitation, and wind speed can be measured. Solving the inverse problem also enables us to estimate the dynamics of state transition, which in turn enables forecasting.

Markov models find applications in a very wide range of domains. They are used in natural language processing for assigning part-of-speech tags to words in a sentence; in

speech processing for identifying the speakers in a long audio stream; in activity recognition to identify a sequence of activities by a person based on readings from wearable sensors; in bioinformatics to find the most likely alignment between sequences of DNA, RNA, or proteins; and many others. Though the initial applications were mostly in the domains of computer science, signal processing, and computational biology, the past decade has seen their uses in other disciplines including earth system sciences.

Variants and Derived Concepts

Various concepts related to or derived from Markov chains are used frequently to solve various problems related to geosciences. Some of the major variants of Markov chains and concepts based on them are discussed below.

Hidden Markov Models

Consider a sequence of observations $\{Y_1, \dots, Y_t, \dots, Y_T\}$. Let us consider this as a random variable which may take values from an *observation space* denoted by y . Y_t is a P -dimensional vector ($P \geq 1$) that may be continuous or discrete. According to the *hidden Markov model*, the unobserved state variable X is a Markov chain over a *discrete state space*, and the observation Y_t follows a distribution over the observation space that is a function of X_t , i.e., $P(Y_t = y | X_t = x) = E(x, y)$. Here $E(x, y)$ is called the *emission distribution* that satisfies $E(x, y) \geq 0 \forall (x, y)$ and $\sum_{y \in \mathcal{Y}} E(x, y) = 1$ (if Y is discrete) and $\int_{\mathcal{Y}} E(x, y) dy = 1$ (if Y is continuous).

The salient feature of this model is that the current system state depends only on the previous state, and the current observation depends only on the current state. This can be succinctly represented by a graphical model, as shown in Fig. 2. These assumptions may be simplistic, but they have an important benefit: they allow efficient and exact inference, i.e., we can exactly compute the distribution $p(X_t | Y_1, \dots, Y_T)$ for any t , and also we can compute the most likely sequence of values of the unobserved state variable, given a sequence of observations.

Markov Chains: Addition, Fig. 2 Graphical representation of hidden Markov model

For specialized applications, various extensions of hidden Markov models are used. The most common one for earth science applications are the *non-homogeneous hidden Markov model*, where the state variable X_t is driven by an additional external variable U_t in addition to its past value denoted by X_{t-1} . In other words, $Prob(X_t = b | X_{t-1} = a, U_t = c) = T(a, b, c)$. $-1 = a, U_t = c) = T(a, b, c)$. This allows the state variable's marginal distribution to vary over time. Another well-known variant is the *factorial hidden Markov model*, where the state space is decomposed into smaller spaces, each represented by separate state variables ($X^1, X^2, \dots, X^K$) in which individual Markov chains are defined. The observation Y is a function of all of these K variables, i.e., $prob(Y_t = y | X_t^1 = x_1, X_t^2 = x_2, \dots, X_t^K = x_K) = E(x_1, x_2, \dots, x_K, y)$.

Markov Chain Monte Carlo

Another important concept based on Markov chains, which is frequently used in the domain of geosciences is *Markov chain Monte Carlo (MCMC) sampling*. This is essentially a sampling technique, which enables us to estimate the posterior distribution of an unknown quantity X , such as the state variable. It is essentially a *Monte Carlo* method of computation through random sampling that is based on the *law of large number* of statistics. The idea is to consider different possible values of the variable X as the states of a Markov chain and estimate the posterior distribution of X as the stationary distribution of such a Markov chain. To estimate this, MCMC methods aim to perform *random walk* over the state space. But this is possible only if there is a transition function from one state to another, and this matter is handled in different ways.

Consider the special case where the conditional distribution of each dimension of X , conditioned on all other dimensions, i.e., $P(X_i | X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_D)$, is known for all $i \in \{1, D\}$, where D is the dimensionality of the variable X . In this situation, we may use *Gibbs sampling*, where we choose any one dimension and sample its value from the corresponding conditional distribution, keeping the values of all other dimensions unchanged. Consider an initial value x_0 of X . Then using the above procedure, we can sample a new value x_1 , where at most one dimension will have a different value from x_0 . This is essentially a transition of the Markov chain. Next we again choose another dimension, sample its value conditioned on the rest, and hence get another sample x_2 . This process is repeated over and over, till we get a large enough number of samples of X that effectively represent the stationary distribution of this Markov chain and hence the posterior distribution of X .

In a more general case where these conditional distributions are not known, but we do know a function $f(X)$ that is proportional to the unknown posterior distribution $P(X)$, we may use another Markov chain Monte Carlo method known

as *Metropolis-Hastings algorithm*. Here too we start with an initial estimate x_0 of X . We choose another candidate value y according to a *proposal distribution* $Q(y|x)$. However, this value is accepted with a probability that is related to its relative likelihood with respect to the current value x_0 , i.e., according to the ratio $\frac{f(y)}{f(x_0)}$. If accepted, we set $x_1 = y$ and then proceed in the same way to get the next sample x_2 . However if y is rejected, then we again sample more values and test them, until one of them is accepted and set as x_1 . Repeating this process enables us to collect a sample set of X which effectively represents the stationary distribution of this Markov chain and hence the posterior distribution of X .

In either case, while collecting the samples, it is necessary to consider samples at regular intervals only (as successive samples are highly correlated to each other). There are also many other algorithms based on the concept of Markov chain Monte Carlo, such as slice sampling. There are also various hybrid methods to enable faster navigation of the state space and focusing on high-density areas (sample with higher likelihood under the posterior P). For a more detailed understanding of these algorithms, the reader is referred to the excellent tutorial paper by Neal (1993).

Applications in Geosciences

Now, we come to case studies of various applications of the above models and concepts in various domains of geosciences, such as climate, hydrology, geology, seismology, and remote sensing.

Hydroclimatology

Hidden Markov models have been used quite extensively for modeling rainfall at hourly or daily spells. The main reason for this is that rainfall usually occurs in spells that may last for a few hours (in case of convective events like thunderstorms), or may hang around for a few days (in case of depressions), and hence the rainfall occurrence and intensity in adjacent time-steps are likely to be related. However, the process of rainfall is dependent on many complex processes in the atmosphere, not all of which can be observed. Hence, it is a common practice in statistical hydro-meteorology to represent the daily/hourly *weather state* as a latent state variable that follows a Markov chain, and the rainfall at any time-step depends only on the weather state at the corresponding time. However, this weather state may be affected by other atmospheric variables like geopotential height, temperature, and relative humidity, which are introduced as external variables affecting the latent state, as in a *non-homogeneous hidden Markov model (NHMM)*. This modeling style was first

introduced by Bellone et al. (2000) and has continued for the next two decades. In these models, the emission distribution of rainfall are usually hybrid: First, a Bernoulli distribution decides whether there is any rain or not, and if so, then the volume is generated by another distribution which may be gamma, exponential, log-normal, etc. In some studies, the parameters of the emission distribution too depend on the external variables.

A more sophisticated application of the same idea is developed by Kwon et al. (2018), where the observations are measurements of soil moisture at multiple sites. The latent variable represents the spatial profile of soil moisture. The covariates or external variables of the NHMM are weather observations like temperature and rainfall. The challenge here is to learn the optimal number of values that the state variable can take, and the parameters related to transition and emission distributions. Successful estimation of the model enables the prediction of soil moisture based on weather forecasts.

Hydrology

In the domain of hydrology, hidden Markov models have been used for modeling daily streamflow sequences in many studies such as Pender et al. (2016). Here, the innovation lies in the emission distribution, which has been specifically designed to model *extreme values* using extreme value distributions like generalized Pareto (GP) and generalized extreme value (GEV). Some of the states signify extreme conditions of streamflow, for which these distributions are used for emission.

Zhang et al. (2018) applied MCMC-based methods in the domain of hydrology, for the purpose of estimating parameters of a groundwater model. They used a Bayesian approach to quantify the uncertainties of the model parameters, conditioned on the magnetotelluric measurements for subsurface salinity of groundwater across a vertical profile. Different types of MCMC algorithms were used to estimate a posterior distribution of the model parameters. In the simple Metropolis-Hastings, a number of sample parameter values were drawn from the prior distribution (based on empirical studies) and accepted or rejected based on the ratio of likelihoods with respect to the hydrological model. In the second approach, an adaptive sampling strategy was considered to navigate the sample space more efficiently, as all accepted samples were used to progressively update the prior distribution. This ensured that samples that are closer to the high-density regions of the posterior are picked, and hence fewer samples are rejected.

Geology and Geophysics

Geostatistics is an important concept in the domain of geology and geophysics which aims to estimate geological values

at any arbitrary spatial location, with the help of a *geostatistical equation*. The geostatistical equation has parameters which may be estimated based on a few locations where the desired variable is measured, using algorithms like *kriging*. However, Oh and Kwon (2001) use a Bayesian approach for estimation of these parameters based on Schlumberger inverse and well log observations of dipole-dipole resistivity. For this, they need a posterior distribution over the parameter space. They first build a *prior* distribution using simulations conditioned on the observations, after which they carry out MCMC sampling of parameter values. They draw samples from the prior distribution, use them to run simulations, compute the error at the points where observations are available, and subsequently accept or discard these samples based on the error. The prior distribution gets updated as more samples are accepted.

Another work by Jasra et al. (2006) considers the use of MCMC approaches to identify the most suitable model parameters, including structural parameters such as number of components in a mixture distribution. They analyze *geo-chronological data* to identify age groups of minerals. The geological properties of minerals from each age group are represented by a component of the mixture distribution. However, the number of mixture components is not fixed but itself a random variable, for which a distribution is estimated using a variant of MCMC sampling called reverse-jump MCMC, which allows for *birth* and *death* of components.

Remote Sensing

Markov chain-related concepts have been considered in the domain of remote sensing too. Harrison et al. (2012) used Markov chain Monte Carlo sampling to estimate posterior distributions on the parameters of land surface models and the uncertainty in simulations of soil moisture by them, by calibrating these models against passive microwave remote sensing estimates of soil moisture. Liu et al. (2021) consider a spatiotemporal HMM for classifying the pixels of satellite image sequences according to land cover types. The spatial consistency of adjacent pixels and the dynamics of temporal changes in land cover are captured through this version of HMM.

Summary and Conclusions

The concept of Markov chain has been developed into models like hidden Markov models and its variants and algorithmic frameworks like Markov chain Monte Carlo. These models and methods find applications in many problems related to mathematical geosciences, especially for forecasting, simulation, and uncertainty estimations. Recent challenges being

explored by the research community are to include spatial and temporal characteristics of processes at multiple scales into these models and applying them in conjunction with deep learning – the state-of-the-art approach being increasingly adopted by researchers of all scientific domain, including geosciences.

Markov Random Fields

Uma Ranjan

Indian Institute of Science, Bengaluru, Karnataka, India

Definition

Most physical phenomena result in structures which have short-range continuity and long-range changes. Such structures are seen in the distribution of rock structures, soil characteristics, temperature and humidity patterns, ore distributions, etc. Even within areas of uniformity or same rock type, there are changes which are random and do not have a spatial structure. Markov random fields are an effective way of characterizing the joint probability distribution of such structures.

Markov random fields are typically defined over a discrete lattice, with an associated neighborhood structure. The neighborhood structure dictates how the value at a lattice point is influenced by the values at nearby sites. Hence, a Markov random fields can also be viewed as a graph whose nodes correspond to the lattice points and whose edges correspond to the neighborhood structure. Such a model, also known as a graph model, combines the power of stochastic models with the computational ease and visualization offered by graph models. MRF are used in several areas ranging from computer graphics to computer vision, classification of images to generating textures. MRFs form an essential part of inverse problems, where characterizing a solution as an MRF allows attractive computational benefits to estimating joint probability distributions.

Introduction

Markov random fields are mathematical models used to solve problems of estimation of quantities. Mathematical models of acquisition of images are well-studied. Digital images of terrain, rock, or earth samples are obtained through different modes of acquisition such as synthetic aperture radar, electron microscopy, or micro-CT. Each of these use certain properties of the object such as surface reflectance, scattering, or absorption to create a digital image, typically representing the spatial distribution of a certain quantity on a discrete lattice. Inverse problems in image processing are those where the properties of an object are inferred from the images. For instance, a camera may record intensities that are reflected, but these observations are modified by blurring and noise. Hence, the true reflectance is the parameter to be estimated from the noisy observations. In satellite imagery, one is interested in identifying the vegetation type at each pixel, which represents

a spatial location. In images of rocks, one is interested in identifying different segments such as rock and pore and sub-types of rocks. Most problems of interest in geosciences are inverse problems.

Inverse problems suffer from the problem of ill-posedness. According to Hadamard (1923), a well-posed solution is one which is possible, accurate, and smooth (shows gradual variations for small variations of input). Most natural systems are smoothly varying; hence, this is a reasonable condition to impose on a solution. Moreover, smooth solutions are easier to handle computationally and represent stability with respect to variations of input, a significant advantage in engineering systems. However, a number of factors beyond our control cause a problem to become ill-posed. Limitations of acquisition systems, different types of noise, and functions used for modeling may cause solutions to be non-smooth. One way to make a problem well-posed is through the use of additional constraints of smoothness which force the solutions to correspond to our assumptions of a well-behaved system. This process is called regularization.

Markov random fields can be represented through probability distributions. This leads to powerful frameworks such as Bayesian inference which can be used to accurately estimate the distribution of the unknown quantities.

Bayesian Inference

One of the most popular methods to obtain regularized solutions to inverse problems is through a probabilistic framework. The variables of interest are assumed to follow a choice of probability distributions.

The notion behind the use of probabilistic distribution is the assumption that the underlying quantity is a well-posed approximation of what is actually seen or obtained from a numerical solution. This uncertainty is modeled as a random variable and forms the fundamentals of the Bayesian approach to inverse problems.

The quantity which needs to be modelled is estimated as a parameter of the probability distribution. In the context of image restoration, the parameter to be estimated is the actual (de-noised) intensity value at each pixel. In an image segmentation problem, the parameter is the class to which each pixel belongs.

The four aspects of Bayesian inverse solutions are:

1. Prior probability distribution
2. An estimated likelihood of the quantity of interest
3. Posterior probability, obtained as a product of the prior probability and the likelihood
4. A loss function, which penalizes an error in the estimate of the parameter of interest

The prior, likelihood and posterior probability are related through the Bayes theorem. If f is the quantity that is to be estimated and g are the observations (such as the acquired digital image), we have

$$Pr\{f|g\} = Pr\{g|f\}Pr\{f\}/Pr\{g\}$$

where $Pr(\cdot)$ refers to the probability function. $Pr\{f\}$ is the prior, reflecting our prior knowledge of the quantity to be estimated. It represents our belief about the distribution of the quantity of interest prior to observing the actual data. The prior probability is defined on the space of values which the quantity to be estimated can take.

$Pr\{g|f\}$ is the likelihood that the observed data fits the prior probability. This represents a “goodness of fit” of the assumed prior with the actual observations. Since the assumed prior is a model of the acquisition system, $Pr\{g|f\}$ is the likelihood function which reflects the fit of the observations to the model. This is also referred to as the degradation model.

The quantity $Pr\{f|g\}Pr\{g\}$ represents the posterior probability distribution. In usual practice, the normalizing constant $Pr\{g\}$ is neglected, since all observations are assumed to be equally likely. Hence, the conditional probability $Pr\{g|f\}$ is often referred to as the posterior probability.

The posterior probability distribution represents an update of our belief about the distribution of the quantity of interest over the lattice. Since the value to be estimated at each point is considered to be a random variable, its actual value is estimated as a parameter of the posterior distribution.

This estimate depends on the loss function that is chosen. The loss function indicates the penalty of choosing a parameter value different from the true value. Different loss functions lead us to different estimators.

For example, minimizing the squared loss function leads to estimating the posterior mean. Minimizing the zero-one loss leads to an estimate of the mode of the posterior (also known as the maximum a posteriori estimate (MAP)). If no information about the prior is available, only the likelihood is maximized, leading to maximum likelihood (ML) estimate.

Ripley (Ripley 1988) showed that the MAP estimate minimizes a variational energy which consists of two terms – one related to data fidelity and the second to a smoothness. The smoothness condition acts as a regularizer. The desired solution corresponds to the minimum of such an energy.

In image processing applications, the posterior probability needs to be estimated over the entire pixel array. When the image sizes are large as in most applications, the posterior probability is computationally intractable. However, when the posterior probability can be modeled as a combination of local interactions, it simplifies the computation of the posterior. This is captured in the notion of a Markov random field, where the assumption is that the information at a point is

dependent only on the information in a neighborhood of a fixed size around a point.

Markov Random Field

If X_s is a quantity of interest (such as intensity, color, texture) that is to be estimated at pixel s in an image S , the Markov property states that the conditional probability of value at a pixel s , estimated from the knowledge of the entire lattice, is the same as the probability of its value, estimated from its neighbors.

$$Pr\{X_s = x_s | X_t = x_t, t \in S\} = Pr\{X_s = x_s | X_t = x_t, t \in N(s)\}$$

X_s is a random variable at pixel location s , and x_s is a specific value that X_s can take. The Markov property thus states that the probability of the value at a pixel s in the image, given the value of X over the rest of the image, is the same as the probability of x_s , given only its neighbors.

The MRF is then a model of the quantity, together with a probability measure which represents the distribution of the quantity of interest. The probability measure is assumed to take values from a pre-determined set $x_s \in \Omega$. These values represent the digitized values of the property (such as color, texture, gradient, or more complex quantities such as class to which the pixel belongs).

The notion of a local neighborhood induces a connectivity structure. For example, in Fig. 1, the central orange pixel is connected to eight neighbors. This configuration is referred to

Markov Random Fields, Fig. 1 Eight neighborhood

as an eight-neighborhood structure. This neighborhood structure is commonly considered to be symmetric, i.e. x is a neighbor of y , and then y is a neighbor of x . Hence, an MRF can also be represented as an undirected graph S, G , where S consists of the set of nodes and G represents the set of edges between the nodes. The graph structure enables the use of efficient computational methods such as graph coloring to perform segmentation tasks on images.

The blue lattice cells are the neighbors of the central orange lattice cells, and the black edges denote the connectivity structure.

The nondirectional nature of the graph representation does not mean that the underlying process which gave rise to the observations is nondirectional. In some cases, the observations may correspond to an underlying drift or diffusion process which could have a direction. The Markov random field in such a case represents the (final) evolutionary state of the underlying process. Hence, an MRF could also be viewed as a snapshot in time of an underlying evolutionary process. This viewpoint has been used in some cases to define hidden factors which correspond to actual physical entities and their evolution, and these factors could in turn influence the observed MRF.

This formulation of the MRF, however, does not directly give us a procedure to actually construct a probability distribution which satisfies the MRF property. A practical way to construct an MRF is given by the Clifford-Hammersley theorem of MRF-Gibbs equivalence:

If an MRF also satisfies the following properties, then it has a joint distribution which is a Gibbs distribution (Rangarajan and Chellappa 1995):

- Positivity: $Pr\{X = x\} > 0$
- Locality: $Pr\{X_s = x_s | X_t = x_t, t \in S\} = Pr\{X_s = x_s | X_t = x_t, t \in N(s)\}$
- Homogeneity: $Pr\{X_s = x_s | X_t = x_t, t \in N(s)\}$ is the same for all sites s in the lattice.

Positivity implies that the values at all pixels are positive, locality is the Markovian property, and Homogeneity implies that the probabilities are independent of spatial location.

The Gibbs distribution is a global property over the entire lattice, given by the following property:

$$Pr(X) = \frac{1}{Z} \exp -\frac{1}{T} U(X)$$

f is a configuration in the sample space, and Z is a normalization constant given by

$$Z = \sum_{X \in S} \exp -\frac{1}{T} U(X)$$

The energy $U(X)$ over the entire configuration X can be factored into energies over smaller, localized set of nodes called cliques.

A clique is defined by a neighborhood configuration in such a way that all the sites in the cliques are neighbors of each other. This offers attractive possibilities of creating computationally efficient means of estimating the MRF. Figure 2 illustrates the possible cliques of two sites in a four-neighborhood and eight-neighborhood of a regular lattice. In the four-neighborhood case, two-site cliques can only be of two orientations, while in the eight-neighborhood case, there are four possible orientations. It is to be noted that Fig. 2b shows only the unique orientations.

Each clique c is associated with an energy V_c , such that the energy of the entire configuration is given by the sum of the clique potentials:

$$\sum_c V_c(X)$$

Gibbs distributions are widely used in statistical physics and have the advantage that they correspond to the minimum value of an energy functional. Thus, the problem of estimating the maximum a posteriori (MAP) estimate is now converted to the problem of estimating the minimum of an energy functional. This enables us to define the energy functional using contextual spatial knowledge for the specific problem.

Factor Graphs

A modification over the MRF is when the variables are not directly observed through a measurement but are inferred from other variables that are observed. For example, fault planes, lithospheric boundaries, or mineral distributions are not directly observed but derived from intermediate variables

Markov Random Fields, Fig. 2 Two-node cliques in different neighborhoods

Markov Random Fields, Fig. 3 MRFs vs. factor graphs. (Reproduced from Bagnell 2021)

such as Potts spins. These intermediate variables are known as latent variables. Latent variables are modeled through the use of factor graphs. Factor graphs make explicit use of latent factors to represent unobserved variables. The neighborhood structure in MRF and Gibbs fields does not specify whether the neighborhood pixels must all be considered simultaneously or pairwise. Factor graphs resolve this ambiguity. In Fig. 3 (reproduced from Bagnell 2021), it can be seen that the ambiguity related to diagonal pixels is easily resolved in the factor graph representation.

Solutions of MRF

Finding the optimal joint distribution of an MRF which minimizes a cost function is in general intractable.

The Gibbs distribution, while offering a way to compute distributions over a local neighborhood, includes a normalization constant which is NP-hard to compute, since it involves a summation over all possible clique energies. However, a number of approximations exist which sample the Gibbs distribution in a manner which does not need a normalization.

An efficient way to estimate the Gibbs distribution on a discrete lattice is through the Gibbs sampler, which is a special case of a Markov chain. This is the basis of the Markov chain Monte Carlo (MCMC) method.

The choice of the prior distribution also has a role in determining the complexity of the solution. In general, it is desirable that the prior and posterior probability distributions have the same functional form. This is guaranteed through the use of conjugate prior functions for the given likelihood function. Normal distributions are a popular choice to ensure conjugate priors.

Some of the methods that have been used for the MAP estimate are:

Simulated Annealing (Geman and Geman 1984): The Gibbs sampler was used to obtain the global minimum of

the energy function which corresponded to the maximum a posteriori estimate. The energy functional is defined over an entire image configuration, and the Gibbs sampler traverses the state space, accepting configurations of a lower energy according to a probability dependent on the temperature. The temperature follows an annealing schedule, which allows the Gibbs sampler to converge in probability to the global optimum solution. This method, while giving very good results, is extremely slow. Some of the later modifications (Ranjan et al. 1998) have focused on reformulating the state-space to accelerate convergence.

Iterated Conditional Modes (Besag 1986): An iterative algorithm was presented, where the value at a point is updated one parameter at a time, while holding the other parameters fixed. This corresponds to a local steepest descent of the conditional probability. This results in a local minimum solution of the posterior probability and has the disadvantage of being sensitive to initial conditions. However, its rate of convergence is fast.

The highest confidence first (HCF) method introduces a confidence measure (stability) for each node. The algorithm starts with a null state at each pixel and terminates at a configuration which minimizes the variational energy. At each step, the stability of a node is computed as an estimate of the local posterior function, i.e., as a combined measure of the observable evidence and a priori knowledge about the preferences of the current state over the other alternatives. The ICM updates only the node with the highest stability. A higher stability denotes an estimate in higher consistency with the observations and a priori knowledge. In this way, the HCF algorithm makes maximal progress towards a final solution based on current knowledge about the MRF.

Belief Propagation: In belief propagation, the interactions between the nodes are modeled as messages being passed between them. The messages represent a state of “belief” of each pixel about the marginal distribution of its neighbor. The messages are updated in a single direction, and the marginal distribution is estimated from a normalized set of beliefs after the messages have converged.

A number of improvements to accelerate convergence and improve memory efficiency have been proposed in recent literature.

Multidimensional dependencies and inter-class relationships have been modeled in the context of geosciences through Markov chain random fields (MCRF) (Li 2007). These are a special category of Markov Random Fields (MRF) where the neighborhood structure is not fixed but may vary in different directions.

Although initial use of the MRF formulation in geosciences was focused on images, it is being increasingly used in more general field settings such as characterization of using the Rayleigh scatter of the Earth's microseismic field (Tsukanov and Gorbatnikov 2018). Thus, the MRF formulation and its accurate solutions are central to developing an increased understanding of the structural and environmental properties of the Earth.

Summary and Conclusions

Spatial data such as images can be modeled through Markov random fields. Obtaining an MRF that satisfies optimality conditions together with constraints that contribute to regularized solutions is a rich field. Many of the approaches that have been used for estimating MRFs have also been presented here. Many of these estimations use stochastic optimization methods to find global minimum solutions.

Recently, deep learning methods have been combined with Markov random field models to provide deterministic solutions to inverse problems. These frameworks provide the advantage of computational scaling along with providing contextual information and capturing higher-order relationships.

MRFs are hence an active area of research in the foreseeable future.

Marsily, Ghislain de

Craig T. Simmons

College of Science and Engineering & National Centre for Groundwater Research and Training, Flinders University, Adelaide, SA, Australia

Fig. 1 Professor Ghislain de Marsily. (Photo by Antoine Meyssonnier 2014)

Biography

Professor Ghislain de Marsily is an internationally renowned scientist famed for his contributions to groundwater hydrology and water management. A highly active member of the French Academy of Sciences, he is currently Professor Emeritus at both the Sorbonne University (Pierre et Marie Curie) and Paris School of Mines, France.

Career Overview

Graduating from the École des Mines as an engineer in 1963, de Marsily went on to complete a doctoral degree in science at Pierre et Marie Curie in 1978. He then proceeded to build a long and distinguished career in hydrology characterized by energy, innovation, and technical mastery. As a hydrologist, Professor de Marsily has researched areas including basin analysis, fluid mechanics, solute transport, waste disposal, river ecology, surface hydrology as well as hydrogeology, water resources management, and global food production. He is a pioneer in the development of stochastic hydrogeology and inverse methods and is the originator of the “hydrogeological national parks” concept to protect the world's dwindling supplies of groundwater. He has collaborated extensively to study groundwater systems throughout the world and has been influential in exploring the hydrology of North Africa together with his African colleagues. He has also worked in India with his former students.

In addition to his personal science, de Marsily has been internationally important in his capacity to build networks and collaborations to address global issues at local levels. In 1989, he established the UMR CNRS SISYPHE, an interdisciplinary research unit involving the National Centre for Scientific Research and the University Pierre and Marie Curie, directing the initiative until 2000. From 1989 to 1999, he established and directed the PIREN-SEINE program at the National Centre for Scientific Research, studying the hydrology of the whole of the Seine catchment area. From 2000 to 2004, he was the founder and director of the Postgraduate School of Geosciences and Natural Resources at Pierre et Marie Curie. From 1994 to 2006, he was a member of the national commission which evaluated research into the management of radioactive waste in France.

Scientific Contribution

Professor de Marsily has made significant and sustained contributions to mathematical geosciences and porous media flow and modeling. He is recognized as a pioneer in geostatistics, groundwater modeling, and approaches for dealing with hydrogeologic spatial heterogeneity. He worked closely with geostatistician Georges Matheron, particularly on a paper dealing with transport in porous media (Matheron and de Marsily 1980). Their paper showed, for the very first time that for the special case of a stratified porous medium with flow parallel to the bedding, that solute transport cannot, in general, be represented by the usual convection-diffusion equation, even for large time. They went on to demonstrate that when flow is not exactly parallel to the stratification, diffusive behavior will eventually occur at large times. They prompted and emphasized the need for further work on the mechanism of solute transport in porous media. This paper was an extraordinary breakthrough triggering a major line of critical scientific inquiry that is of profound importance to groundwater science and to mathematical geosciences to this day. It has altered our understanding of groundwater flow and solute transport behavior, demonstrating for the first time the ways in which diffusion and dispersion act to control those processes. The Matheron and de Marsily (1980) paper has become a seminal work in hydrogeological science. Cited 731 times (Google Scholar 25 March 2021), it remains one of the most cited papers in groundwater science to this day.

de Marsily's impact extends well beyond his own research. He has been a driving force in communicating and teaching groundwater science to students and professionals around the world. His textbook *Quantitative Hydrogeology: Groundwater Hydrology for Engineers* (de Marsily 1986) is a classic text in groundwater science. It is a unique book, placing great emphasis on both qualitative and quantitative hydrogeology.

As noted in its preface: "the qualitative and the quantitative aspects are not treated separately but combined and blended together, just as geology and hydrology are woven together in hydrogeology." This was, and remains, a simple but profound observation that has done more to shape the field of hydrogeology than many research papers. It reflects de Marsily's keen interest and success in understanding concepts and to ensure that they are treated physically, mathematically, and philosophically in a robust and rigorous manner. The textbook is still in its first and only edition and remains in print to this day, with 3161 citations (Google Scholar 25 March 2021) – and growing.

Professor de Marsily remains an energetic, inspirational, and provocative scientist, a visionary thinker, and a world leader in groundwater research. He has inspired, mentored, and taught generations of researchers and students while making a remarkable impact on all aspects of hydrogeology research, education, policy, and management. Emphasizing the vital relevance of science to society, he has both made and inspired important contributions to some of the most critical environmental debates of our time, including critical planetary-scale insights into water, climate change, food and population growth, and nuclear waste disposal.

Awards and Honors

Recognizing his outstanding contributions to hydrogeology, including his legendary lectures and numerous books on hydrogeology, fluid transport, and geostatistics, de Marsily has received many awards, including the O. E. Meinzer Award of the Geological Society of America, Robert E. Horton Medal of the American Geophysical Union, and the President's Award of the International Association of Hydrogeologists. In addition to these honors, de Marsily is Chevalier de la Légion d'Honneur, a Member of the French Academy of Sciences, French Academy of Technologies, French Academy of Agriculture, and a foreign Member of the US National Academy of Engineering. In recognition of his scientific achievements and significant contributions to hydrogeology, de Marsily was awarded the degree of Doctor of Science *honoris causa* from Flinders University (Australia), University of Neuchâtel (Switzerland), and University of Québec (Canada).

Mathematical Geosciences

Qiuming Cheng

School of Earth Science and Engineering, Sun Yat-Sen University, Zhuhai, China

State Key lab of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China

Definition

Mathematical geosciences or geomathematics (MG or GM) is an interdisciplinary field involving application of mathematics, statistics, and informatics in earth sciences. The International Association for Mathematical Geosciences (IAMG) is a unique international academic society with mathematical geosciences as part of its title and the mission of which is to promote, worldwide, the advancement of mathematics, statistics, and informatics in the Geosciences. However, the lack of a unified definition of mathematical geosciences or geomathematics (MG or GM) as an interdisciplinary field of natural science may lead to misunderstanding of the subject or not even treating it as an independent discipline. This has, to some extent, affected the development of the field of mathematical geosciences. Since late 1990s, the author of the current chapter has served IAMG as capacities of, council member, vice president, and president. Thus, the author has witnessed and contributed to the transformation of IAMG from Mathematical Geology to Mathematical Geosciences, as well as various updates of IAMG associated publications including journals and conferences proceedings. In 2014, in his IAMG president column in the newsletter, the author discussed about a definition and connotations of mathematical geosciences as well as demonstration of contributions of mathematical geoscientists and frontiers of mathematical geosciences. Mathematical Geosciences was defined as an interdisciplinary scientific subject that integrates mathematics, computer science, and earth science, and it is the study of the mathematical characteristics and processes of the earth (and other planets) and the prediction and analysis of its resources and evaluation of environment.

Introduction

The International Association for Mathematical Geosciences (IAMG) is a unique international association with the term of Mathematical Geosciences as its title and the mission of promoting application of mathematics, statistics, and informatics in earth science. IAMG was initially established with its title of International Association for Mathematical Geology in 1968 at the 23rd International Geological Congress

(IGC) and in affiliation to the International Union of Geological Sciences (IUGS) and the International Statistical Institute (ISI). In addition to Mathematical Geology, Geomathematics and Geostatistics were also suggested to be used as its name. Some books and series of monographs published by the IAMG members in the field of mathematical geology also used these names. For example, the books authored by Frits Agterberg and published by Springer use geomathematics as book titles: the book “Geomathematics: Mathematical Background and Geo-science Applications” in 1974 and the book “Geomathematics: Theoretical Foundations, Applications and Future Developments” in 2014. Since mathematical geology could be literally interpreted as a branch of geology, some government Natural Science Foundations also group mathematical geology as a subdiscipline of geology. With the continuous development in the field, the applications of mathematical theory and methods as well as relevant software systems are no longer limited to geology. They are also widely used in other fields of geosciences including but not limited to hydrology, geophysics, and geochemistry. To serve the community better and to represent the complete connotation of the discipline, during the General Assembly of IAMG at the 33rd IGC held in Oslo in 2008, the name of the Association was changed from International Association for Mathematical Geology to International Association for Mathematical Geosciences with the same abbreviation IAMG. Accordingly, it revised the names of journals, for example, the flagship journal “Mathematical Geology” was renamed as “Mathematical Geosciences.” Thus, the three journals of IAMG that time include *Mathematical Geosciences*, *Computers & Geosciences*, and *Natural Resources Research*. Since then, these journals and IAMG annual conference proceedings have published works with more variety of mathematical geoscience topics. The name change of the association must be important in broadening and expanding the application fields of mathematical geosciences. One example worth mentioning is that IAMG established an affiliation with the International Union of Geodesy and Geophysics (IUGG). In this way, the international alliance to which IAMG is affiliated has expanded to include the International Union of Geological Sciences (IUGS), the International Union of Geodesy and Geophysics (IUGG), and International Statistics Institute (ISI). These three international organizations are large and active union members of the International Science Council (ISC). They cover most of the disciplines of earth sciences, mathematics, and statistics. Establishing affiliations and actively engaging in activities with these Unions have broadened the IAMG’s international collaboration which in turn enhanced its international visibility and influence in the mainstream earth science community. Now IAMG fully represents a branch of geosciences rather than only geology.

It should be noted that Mathematical Geosciences (or Geomathematics), as a relatively young earth science discipline, still has not been widely accepted by the mainstream field of geosciences and is even often ignored. On the one hand, it may be due to the organization of the association which has relatively small number of registered members. On the other hand, it may be because the society does not have a clear subject definition and connotative boundaries, especially the unclear subject boundaries with other related disciplines. Without a clear definition of the Mathematical Geosciences subject, those who indeed work in the fields of mathematical and statistical geosciences are not considered as mathematical geoscientists rather as geodesists, geophysicists, etc., and their work and academic contributions are not regarded as mathematical geosciences. For example, the section of this chapter will introduce an internationally renowned scientist Professor Dan McKenzie of Cambridge University in the United Kingdom. He is a physicist and mathematician by education and training. In the 1960s, he combined mathematical thermodynamics with geoscience and systematically established thermal structural models for describing plate tectonics and mantle dynamics. Because of his pioneering and groundbreaking work in the formation of plate tectonics theory, Professor Dan McKenzie is praised as one of the four major contributors to the development of the modern plate tectonics theory (<https://geolsoc.org.uk/Plate-Tectonics/Chap1-Pioneers-of-Plate-Tectonics/Dan-McKenzie>). McKenzie's work is well known in the fields of geophysics and tectonics, and he is also considered as a geophysicist rather than a mathematical geoscientist.

Although several descriptive disciplinary definitions and terminologies about mathematical geosciences have been proposed in the literature, there is still a lack of systematic, inclusive, and relatively standard disciplinary definition. For example, mathematical geosciences are often referred to simply as the application of mathematical and statistical methods in geology (or in earth science), or the application of geological data analysis and quantitative prediction model development (Howarth 2017). The IAMG website once defines the mission of IAMG as: to promote the development and application of mathematics, statistics, and informatics in earth sciences. In the author's view to define Mathematical Geosciences (MG) as a formal subject, or to simply define it as the application of mathematics, statistics, and informatics in the Earth sciences, is a fundamental question that has a vital impact on the development of the subject. For this reason, during his presidency of IAMG, the author of current chapter attempted to propose a definition of mathematical geosciences. It was published in as president forum on Newsletter (Issue 76–79) (Cheng 2014). Here I will elaborate on the definition of MG and give several examples to demonstrate the contributions MG made to geosciences.

What Is Mathematical Geoscience (MG)?

As mentioned earlier, Vistelius (1962) gave an earlier definition of mathematical geology and used it as the name of the Association. Geostatistics is a remarkable new subject of mathematical geology developed by IAMG scholars. Now the geostatistical theory and methods have been used not only in earth sciences but also in many other scientific fields. Geostatistics was once refereed as the application of statistical methods in geology or other geosciences (e.g., Merriam 1970; McCammon 1975), and in many cases this simple definition seems to be still in use. As mentioned in previous section, the term Geomathematics has also been used by several authors including Agterberg (1974), who used the term as the title of his two books (Agterberg 1974, 2014). Since the IAMG changed its name from Mathematical Geology to Mathematical Geosciences in 2008, the term Mathematical Geosciences has often appeared in IAMG's literature including books, conference proceedings, and journals. The difference between mathematical geology and mathematical geosciences is not only in terms but also in the connotation and scope of the subject. If mathematical geology is a branch of geology, mathematical geosciences should be an interdisciplinary subject of geological sciences, and it must include mathematical geology as one of the branches of mathematical geosciences. Compared with geology, geosciences also cover other related disciplines including but not limited to geochemistry, geophysics, geobiology, and hydrology. Mathematical geosciences should be a branch of geosciences parallel to other cross-disciplines in earth sciences such as geochemistry, geophysics, and geobiology, rather than a branch of geology (Fig. 1). In the author's opinion, this distinction is very important for the development of the subject. For example, under the concept of mathematical geology, the subject is limited to the application of mathematics, statistics, and informatics in geology, but as a subject of mathematical geosciences, similar to geochemistry and geophysics, MG serves the entire geosciences. So, what should be the definition of mathematical geosciences or geomathematics? What role should mathematical geosciences play in the earth science family? What are the major contributions of mathematical geoscientists to the development of earth science? What are the frontiers of mathematical geosciences today? In the future, how will mathematical geosciences develop in the context of the rapid development of big data, artificial intelligence, and other new mathematical theories? These questions are of interest to mathematical geoscientists who must provide answers, especially for the younger generation of students and researchers in geosciences. The following is a summary of the author's thoughts during the past years about the above questions related to mathematical geosciences.

Mathematical Geosciences,

Fig. 1 Schematic diagrams showing the relationship between natural sciences and earth science (a) and how mathematical geosciences works (b)

To give a definition of mathematical geosciences, we might as well understand the situation of other related interdisciplinary subjects, such as geochemistry, geophysics, and geobiology.

According to the descriptions in Collins English Dictionary, Geophysics is referred as “a science of studying the earth’s physical properties and the physical processes acting upon, above, and within the Earth.” Similarly, Geochemistry is a science that deals with the chemical composition of and chemical changes in the solid matter of the earth or a celestial body (Unabridged dictionary). Finally, Biogeosciences is referred as an interdisciplinary field of integrating geoscience and biological science: the study of the interaction of biological and geological processes (Unabridged dictionary). The above definitions emphasize on interdisciplinarity of intersection of basic natural sciences and earth sciences. Similarly, we can define mathematical geosciences as an interdisciplinary scientific subject that integrates mathematics, computer science, and earth science, and it is the study of the mathematical characteristics and processes of the earth (and other planets) and the prediction and analysis of its resources and evaluation of environment (Cheng 2014). The core issues of the new definition are the characteristics and processes of the earth. The concepts of chemical and physical properties of the earth, and chemical, physical, and biological processes of the earth are relatively easy to understand and so do the definitions of geochemistry, geophysics, and geobiology. But what are the mathematical characteristics, properties, and processes of the Earth? And why is the prediction and evaluation of the earth’s resources and environment inherently related to mathematics? These are key questions to answer to convince that mathematical geosciences can be regarded as an independent but interdisciplinary discipline which distinguishes it from other related disciplines. So, let’s first review the main differences among mathematics, physics, and chemistry. Most people started to learn these basic natural courses in elementary or middle schools. Chemistry is mainly about studies of composition, properties, structure, and change laws of matter at the molecular and atomic microscopic level; physics is mainly concerned with studies of physical properties and processes

of matter, including the most general laws of motion and basic structure of matter; and mathematics can be referred as studies of quantity, structure, change, space, information, etc. The integrations of these basic disciplines and earth sciences form various interdisciplinary geoscience subjects such as geochemistry, geophysics, geomathematics, and geobiology. Actual integration of multiple branches of basic sciences such as chemistry with earth science has formed various sub-disciplines of geochemistry, including major element geochemistry, trace element geochemistry, stable isotope geochemistry, and isotope chronology. Various analytical and testing techniques developed in the field of chemistry have been adopted into geochemistry such as mass spectrometry, fluorescence analysis, and laser ablation imaging technique. Similarly, multiple branches of physics are integrated with earth sciences to form multiple geophysical directions, such as gravity, magnetism, electricity, semiology, radioactivity, superconductivity, and other geophysical directions. Accordingly, various types of physical detection and survey technologies have been developed and applied in geosciences, including gravitational measurement, nuclear magnetic resonance, magnetic measurement, seismic measurement and electrical measurement. Similarly, various mathematical disciplines such as geometry, calculus, power spectrum analysis, morphology, topology, probability and statistics, and fuzzy mathematics can provide indispensable theories and methods for quantitative studies of relevant properties of the Earth. The characteristics and properties of the Earth that must be studied by means of mathematics include but not limited to the geometric characteristics, dynamic characteristics, the uncertainty of earth observation and measurement, the prediction error of earth events, and so on. These important issues related to the Earth are all mathematical problems in nature which cannot be studied without mathematics. Therefore, the integration of these subdisciplines of mathematics with geoscience forms different directions of mathematical geosciences. For example, the integration of probabilistic statistics and geosciences produces results in a new subject of geostatistics and the integration of calculus and geosciences creates a subject of

mathematical geodynamics. Theories and methods developed in Geometry can be used in earth science research to solve various geometric problems of the earth, such as the shape, coordinates, angle, length, volume, quantity, distance, and direction of the Earth. Many examples can be cited to demonstrate effective utilization of various mathematical theories and methods in solving geoscientific problems. In the next section, some selected examples will be introduced to show how mathematical geoscientists have played an important role in earth science research, what significant contributions that mathematical geoscientists have made in the development and advancement of modern earth science theories and solving applied problems related to sustainable development, and how they will continue to play an important and irreplaceable role in the innovation of earth science in the future.

Examples of Important Contributions of Mathematical Geoscientists to Earth Science

There are many examples to show how mathematical geosciences and mathematical geoscientists have made indispensable and fundamental contributions to the development of modern earth sciences. Here just name a few examples.

Earth Geometry

The geometric shape of the Earth is an important property of the Earth which serves the base for quantitative earth science. Mathematical models of the shape of the earth, such as Clark ellipsoid and Hayford ellipsoid, are the basic geodetic models for positioning and navigating systems (such as GPS and BDS) and other types of remote sensing technology (RS) for spatial measurement and spatial analysis. The shape of the earth is irregular and complicated, but in order to establish an earth coordinate system, a mathematical model needs to be used to approximately represent the shape of the earth, which is the earth ellipse (Ellipsoid or Spheroid) (Fig. 2). The equation of the ellipsoid in the Cartesian coordinate system is:

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \quad (1)$$

where a and b are the equatorial radius along the x and y axis, and c is the polar radius along the z axis. These three parameters determine the shape of the ellipsoid, including the flatness or flatness rate of the earth's ellipse. To elaborate on the relationship between the ellipse and the Geoid is beyond the scope of this chapter. The point worth mentioning is that the shape of the Earth is indeed a mathematical feature of the Earth. As a matter of fact, the first to establish the earth ellipse model and name it Geodesy was the British scholar Alexander Ross Clarke (1828–1914). He is an internationally renowned mathematician and geodesist. His important contributions

Mathematical Geosciences, Fig. 2 The mathematical model of the geometric shape of the earth as an ellipsoid

include the calculation of the British Geodetic Triangulation (1858), the calculation of the shape of the Earth (1858–1880), and the publication of a monograph on Geodesy (1880). This is an excellent example done by a pioneer mathematical geoscientist for modeling the geometrical property of the Earth.

Age of the Earth

The age of the Earth is a curious question of the earth science. Before the invention of isotope geochemistry there was no consistent answer about the age of the Earth. One of the well-known estimates of the age of the earth was given by William Thomson, 1st Baron Kelvin (1824–1907), a British mathematician, mathematical physicist, and engineer. Kelvin estimated the age of the Earth by investigating the Earth's cooling and making historical inferences of the Earth's age from his calculations. Kelvin calculated how long it would have taken Earth to cool if it had begun as a molten mass. Kelvin made several assumptions about the earth to set his conductive model for estimating the age of the Earth. These assumptions include that the Earth's heat was originally generated by gravitational energy; for a short period of time, say 50,000 years the Earth cooled from a temperature of about 3700 °C to the present temperature of about 0 °C; since then, the average temperature of the Earth's surface has not changed significantly; and the interior of the Earth is solid and a secular loss of heat from the whole Earth through heat conduction. Kelvin established a heat conduction equation from which he derived an estimate of 20–40 million years of age of the Earth. While his estimate was proved wrong by the discovery of radioactivity and the radioactive dating technology which yields an estimate of 4.54 billion years old, his heat conduction model of the Earth based on observations and calculations was an accurate and similar conduction models have been applied in other fields of geodynamics including in

simulating heat flow processes in mid-ocean ridges as to be introduced in later section of the chapter. William Thomson is also well known for his work in the mathematical analysis of electricity and formulation of the first and second laws of thermodynamics. Kelvin's work in relevance to the topic of the current chapter is also due to the term of "Mathematical Geology" was used, might have been for the first time in the literature, as the title of review paper introducing Kelvin's work in Nature by Lodge (1894).

Geodynamics of the Plate Tectonics

The modern plate tectonics theory being advanced in the 1960s has become a profound revolution in the field of earth science, which provides scientific explanations about evolution of the Earth systems and formations and distributions of major geological events such as earthquakes, volcanoes, magma, and orogeny as well as minerals, water, and energy resources. It is believed that the theory of plate tectonics has completely revolutionized the global view of the solid earth and promoted the formation and development of the concept of the earth system sciences.

The pioneers who have made important foundational contributions to modern plate tectonics theory include but not limited to Dan McKenzie of Cambridge University in the United Kingdom, Jason Morgan of Princeton University in the United States, Professor Xavier Le Pichon of France and Professor Tuzo Wilson of the University of Toronto in Canada. Among them, Dan McKenzie is an eminent geophysicist and geomathematician. Professor McKenzie received a scholarship in mathematics and entered the natural sciences in university in his early age. He had systematically studied mathematics, physics, chemistry, and geology, and graduated with a doctorate at the age of 23. He had creatively applied Euler vector theorem and calculus to describe geodynamics of earth plate tectonics and achieved remarkable results which demonstrate the essential role of mathematics in the establishment of plate tectonics theory.

Mathematical Principles of Plate Tectonics

Dan McKenzie's most influential result was the paper he published in collaboration with Robert Parker (McKenzie and Parker 1967). This paper uses Euler's rotation theorem to prove the conjugate relationship of the three sides of rigid plates: mid-ocean ridges, subduction zones, and transform faults. Euler's rotation theorem shows that a rigid body (such as a plate) is displaced in three-dimensional space, and at least one point inside it is fixed. The displacement of a rigid body is equivalent to a rotation around a fixed axis containing the fixed point (Fig. 3). This achievement is praised by colleagues as the mathematical principle that defines plate tectonics on a sphere, the most theoretical work of the plate tectonics.

Mathematical Model of Mantle Convection

Another influential paper by McKenzie (1967) is the result of the heat flow and gravity anomalies in mid-ocean ridges. This model modified the seafloor expansion model established by the American scholar Harry Hess (1960) and established the mid-ocean ridge heat flow diffusion model and the mantle convection mathematical model. This work had laid the foundation for a series of geodynamic models subsequently developed in the field of plate tectonics for characterizing plate tectonics including thermal structures of plates, subducting slab dynamics and dynamics of basin formation. Figure 4 shows the parameters and boundary conditions of the McKenzie model. The plates on both sides of the mid-ocean ridge are regarded as constant rigid bodies with regular boundaries, with constant expansion speed (V) and gradual change of thickness (a), and the boundary conditions of temperature (T_1) on bottom boundary and temperature (T_0) on top boundary of the plate (lithosphere). Under some simplifications, the heat flux can be expressed by the following diffusion equation:

$$\frac{\partial[\rho C_P(T)T]}{\partial t} = \frac{\partial}{\partial z} \left(k(T) \frac{\partial T}{\partial z} \right) \quad (2)$$

where ρ the mass density of the lithosphere; T temperature; C_P specific heat capacity; t time; k thermal diffusivity; and z depth. The upper left picture in Fig. 4 shows the mid-ocean ridge heat flow diffusion model and boundary and initial conditions established by McKenzie (1967). The upper right picture in Fig. 4 shows the comparison between the actual measured heat flow results and the theoretical prediction results using the McKenzie model. The difference between the two results is relatively large. Many authors believed that the difference is due to the heat loss caused by the convection of hydrothermal fluid near the mid-ocean ridge. Starting from the complexity and fractal structure of the mid-ocean ridge lithosphere, the author of this book chapter substituted the lithospheric density in the McKenzie model with the fractal density proposed by the author and re-established the diffusion model. The re-established diffusion model significantly improved the results for prediction of heat flow (Cheng 2016). McKenzie and many later authors established basin formation models based on plate thermal diffusion models, slab thermal structure, subduction models, etc. Cheng (2016) and subsequent series of results have demonstrated that classical mathematical models such as thermal diffusion are effective for smooth, gradual and linear geological processes, but they are less effective in simulation of singular, abrupt, and nonlinear geological processes and geological events. For the latter, the fractal density and the principle of singularity need to be used. This will be introduced in Sect. 3 of the chapter.

**Mineral Crystals**

Mineralogy is a basic subject of geological sciences. Chemical composition and crystal structure determine the physical and chemical properties of a mineral. Crystallography is a subject of study of the crystal structure of the atomic arrangement of minerals. At the microscopic atomic level, the crystal structure of a mineral can be expressed as a crystal lattice, the smallest unit of a crystal at the molecular level. Therefore, the geometric shape and mathematical properties of the crystal lattice are important parameters for determining the properties of minerals and for minerals classification. Mathematics has played an irreplaceable role in studying the crystal lattice.

Due to the significant contributions of scientists in the field of crystals, crystallography has become a new branch of mathematics. Mathematical crystallography is still a very active field of research today (Nespolo 2008).

Mathematical System of Lattice and Crystals

There are many international distinguished scientists and mathematicians who work in the field of crystallography. Here just name a few examples: German mineralogist, physicist, and mathematician Christian Samuel Weiss (1780–1856) was a pioneer who made fundamental contribution to the modern crystallography. He established crystal

Mathematical Geosciences, Fig. 4 The mid-ocean ridge heat flow model by McKenzie. (Adapted from McKenzie 1967). (a) Model boundary conditions; (b) comparison of McKenzie model theoretical curve and

observed data, showing large deviations between the two; and (c) heat-flow profile showing much improved agreement with a new model (by author) using fractal density (black line)

systems and a classification scheme based on crystallographic axes (Fig. 5). He established the Weiss crystal face index or later called the Miller crystal face index (Weiss indices or Miller indices) and their mathematical algebraic relationships (Weiss 1820), which has been termed Weiss's zone law that has been used till today (Fig. 5). Another giant scientist whom I cannot fail to mention is the French physicist and statistician Auguste Bravais (1811–1863). He is not only a great physicist but also an outstanding statistician. He has taught a course in applied mathematics to students of the Department of Astronomy in the Faculty of Natural Sciences since 1840. Bravais published a paper on statistical correlation in 1844 which later became known as the famous Karl Pearson correlation coefficient. Today the Pearson correlation coefficient is still the most used statistical method to measure correlation in natural sciences, social sciences, and economics. Bravais also studied the observation error theory and published the research results of the mathematical analysis of error probability in 1946. Of

course, the most known academic contribution of Bravais is the work on crystallography, especially the lattice system established in 1848 (Fig. 5). He mathematically proved that there were 14 unique lattices in three-dimensional crystalline systems, which were later called Bravais lattices.

Crystal Lattice Symmetry and the Mathematical System of Mineral Classification

The physical and chemical properties of minerals are not only dependent on their chemical compositions but also constrained by their crystal structures. Crystal symmetry refers to the property of the repetition of the same part of a unit cell. It must be achieved through a certain symmetry operation. Crystal symmetry is a primary geometric characteristic of the crystal lattice that has been found as an essential attribute that affects the physical and chemical properties of minerals, such as the optical properties of minerals. There are three types of symmetry operations: rotation, reflection, and

Mathematical Geosciences, Fig. 5 Crystallographic systems. (a) Symmetry of crystal unit cells; (b) crystal systems; (c) Weiss or Miller indices

inversion. Each kind of symmetry can be expressed by a symmetry element, and various combinations of symmetry elements form multiple but not independent combination types. In 1830, the German mineralogist Johan Friedrich Hesse used mathematical deduction to study the symmetry operation and mathematically proved that there are 32 independent crystal symmetries. Thus, mineral crystals should be divided into 32 groups (Bradley and Cracknell 2009). However, the 32 groups of minerals were not completely observed at that time, and it was gradually conformed later. This indeed indicates that answers for complex issues could be predicted when proper mathematical models and laws are established.

Sedimentology-Mathematical Index of Sediment Grain Size Classification

Sedimentology is a basic geological discipline for studying sediments including exploring the origin, transport, deposition, and diagenetic alterations of the materials that compose sediments and sedimentary rocks. The grain size and its distribution of sediments can reflect the lithofacies and paleogeographic environment as well as other mechanisms, such as transportation, sorting, suspension, and deposition. The grain size may also affect other properties of sediments such as porosity, permeability, load intensity, and chemical reactivity. Therefore, grain size analysis is a primary task in sedimentology. According to grain size of sediment, sedimentary rocks are classified as: mudstone (<0.0039 mm), siltstone ($0.0039 \sim 0.0625$ mm), sandstone ($0.0625 \sim 2$ mm), and conglomerate ($2 \sim 256$ mm). Such a classification scheme was originally established based on the Udden classification (Udden 1898) and Wentworth classification (Wentworth 1922). Later, William Christian Krumbein proposed in 1934 the well-known phi (ϕ) scale based on logarithmic transformation of particle size (Krumbein 1934). The particle scale phi (ϕ) provides a quantitative index for the Udden-Wentworth scale grain size classification and laid an important foundation for quantitative classification of sedimentary rocks. Krumbein also published a series of papers in mathematical geology including various indexes for shape measurement and characterization of sediment particles. These works have played a fundamental role in the establishment of the discipline of mathematical geology. Therefore, William Christian Krumbein owned his name as the father of mathematical geology. The International Association for Mathematical Geosciences has established the highest award in the field of mathematical geosciences under the name of William Christian Krumbein.

Foundation of Geographic Information System: Topological Data Model

Topology was established in the mid-seventeenth century by the Swedish mathematician and physicist Leonhard Euler. Topology is a branch of mathematics that studies geometrical

objects that are preserved under continuous deformation. Simple topological relations include orientational relations (such as inside and outside, up and down, left and right), connectivity and directionality, etc. Topological theories and methods are widely used in many fields of natural science (Richeson 2008). For example, the concept of topology has been used in geographic information system (GIS) for organizing spatial data in topological data model and for spatial topological relationship analysis. The capability of handling topological relations for spatial information analysis distinguishes GIS from other computer graphics and image processing systems.

Fundamental Laws of Geochemical Element Distribution

Geochemistry is an interdisciplinary subject of earth science that has developed rapidly in recent decades. The concept of geochemistry was first developed by the German chemist Christian Friedrich Schönbein in 1838, but in the following decades, people still used to call it chemical geology. When it comes to modern geochemistry, we have to mention two founders who are very familiar to all. One is the American chemist Frank Wigglesworth Clarke (1847–1931), and the other is Norwegian mineralogist Victor Goldschmidt (1888–1947). Clark discovered the relationship between the abundance and content of elements in the earth's crust through statistical analysis of a large amount of data, and published a Book entitled "The data of geochemistry" in which the term "Clark Values" was soon widely accepted (Clarke 1920). Clark himself is thus praised as the father of modern geochemistry. The Geochemical Society established its Young Geochemist Award under Clark's name (Mason 1992). Clark also used statistical theory and the least square method in his other research.

Victor Goldschmidt studied inorganic chemistry, physical chemistry, geology, mineralogy, physics, mathematics, and botany during his time at the University of Norway. He proposed rules and standards for the classification of elements. His findings published in the series of books "Geochemical Laws of the Distribution of Elements" have a long-term impact on modern geochemistry. Victor Goldschmidt is praised as the father of modern geochemistry. The Geochemical Society established the highest award in the field of geochemistry under the name of Goldschmidt (Mason 1992). The study of the distribution law of geochemical elements has opened a new research direction for mathematical geosciences. The research on this topic boomed in the 1950s and 1960s. For example, the normal distribution and/or lognormal distribution were believed to be the fundamental law of determination of rock geochemical elements (Ahrens 1953). This widely accepted statistical distribution model lays the foundation for the applications of statistical theories and methods in geochemical data analysis. For more than half a century, statistical theory, statistical models, and statistical

methods have been commonly utilized in the field of geochemistry. These include but not limited to geochemical data error analysis ($\pm 2\sigma$), geochemical element correlation analysis (R^2), statistical inferential analysis, exploratory analysis, statistical reasoning, statistical discrimination, multivariate statistical analysis, anomaly and background separation, geochemical pattern recognition, and geochemical process or mechanism modeling. However, whether normal distribution or lognormal distribution is proper for all situations of the geochemical elements has also been questioned (Aubrey 1954). Aubrey (1954) found that the distribution of certain elements in coal samples deviated from normal or lognormal distribution. What should be the basic law of the distribution of geochemical elements has also become a basic scientific question in the field that has been unresolved for a long time. The author of the chapter and his PhD supervisor Frits Agterberg analyzed the geochemical data from normal rock samples and from mineralized rock samples and they found that the element concentration in normal rock samples can be described by normal or lognormal distribution, while data from samples collected in the mineralized alteration zones deviate from the lognormal distribution (Cheng et al. 1994). Further it was revealed that the relationship between intensity of ore elements anomaly in the alteration zones and the areas of the anomaly with various thresholds depicts self-similarity which can be described by the following “Concentration-Area” (C-A model) fractal model (Cheng 1994).

$$C(A) = cA^{-\Delta x/2} \quad (3)$$

where A represents the abnormal area, and $C(A)$ represents the average element concentration within the area A . A variety of mineralization-related elements (such as Au, Cu, As, Pb/Zn) depict the above power law relationship between the area and the average concentration values. The model provides a mathematical formula quantitatively describing the abnormal enrichment law of ore-forming elements in the mineralization district for the first time. The idea and power law model were utilized to describe geochemical distribution and to effectively distinguish between “geochemical anomaly” and “geochemical background.” This original idea and C-A fractal model has opened important new direction of quantitative research on identification of geochemical anomalies and separation of anomaly from background (Cheng 1994). The theoretical background of the C-A model is the extreme value statistics and singularity of multifractal theory. Multifractals can be considered as a generalized model which describes more complex distributions than normal or lognormal distributions of values with multiple scaling properties. Multifractals can simultaneously describe a normal distribution or a lognormal distribution of values around the mean and power-law distribution or fractal long-tailed distribution

of values along two tails. Therefore, multifractal distribution model unifies the normal distribution, lognormal distribution and Pareto’s distribution or Zipf’s law distribution (Fig. 6). Multifractals thus can be used as a general and prime distribution model for geochemical values. So far, the C-A method and the expended forms have wide applications in geochemical data analysis for mineral resources assessment and mineral deposits prediction. This method has been demonstrated as one of the most effective methods in mineral resource prospecting and environmental assessments. The paper (Cheng et al. 1994) is one of the most cited papers in *Journal of Geochemical Exploration*.

Quantitative Prediction and Assessment of Mineral and Energy Resources

Quantitative description, simulation, and prediction in geosciences are the fundamental objectives of mathematical geosciences, which require reasonable mathematical models as foundation. Mineral, water, and energy resources are the basic elements for social and economic development. The increasing demands for natural resources for the sustainable development and improving human life quality require solutions for supplies of mineral, water, and energy resources and for green utilization of natural resources in protecting environment and ecological systems. The main tasks of quantitative prediction and assessments of natural resources (minerals, water, and energy) may include but are not limited to determining potential locations of resources, estimating amounts of resources, and evaluating economic values and development feasibility. These results can provide supports for the government or industry in informative decision-making in planning and development of mineral, water, and energy resources. Due to the complexity of formation mechanisms and the distribution of natural resources and the limitations of human intelligence, there are still strong uncertainties in the quantitative prediction of natural resources (Singer and Menzie 2010). Since the establishment of IAMG, the quantitative assessments of mineral and energy resources have always been an important research field of the society. A series of predicting theories and methodologies have been successively developed and widely used. For example, researchers at the Geological Survey of Canada (GSC) have developed theories and methods including weight of evidence model, fuzzy logic, neural network, and logistic regression for comprehensive data integration for mineral potential prediction (Agterberg 1989); the researchers at the US Geological Survey (USGS) have developed and applied a “three-step” mineral resource assessment method [34]; and Chinese scholars have developed predictive methods on the basis of the principle of genetic association of geological anomaly and metallogeny (Zhao 1998, 2002), synthesis of comprehensive information for mineral resource

Mathematical Geosciences, Fig. 6 Law of geochemical distribution of the geochemical elements. (a) Separation of anomalies ($>2\sigma$) based on normal or log-normal distributions; (b) pattern delineated according

prediction (Wang et al. 1990), and nonlinear methods for mineral resources prediction on the basis of fractal singularity theory (Cheng 2007b, 2008). In recent years, exploration for mineral, water, and energy resources has become the forefront of geoscience due to the shift from traditional areas for shallow and low-cost resources to nontraditional regions such as deep earth, remote areas, covered areas, deep ocean, and deep space for strategic resources including critical minerals. Here are just a few examples to show the recent activities of resources assessments in nontraditional areas, and USGS

conducted a statistical assessment of oil and gas resources in the Arctic in 2009. The results of the study show that about 30% of the world's undiscovered gas and 13% of the world's undiscovered oil may exist in Arctic (Gautier et al. 2009). In 2018, Japanese scholars reported discoveries of considerable amounts of rare-earth elements and yttrium (REY) resources in deep sea mud in the western North Pacific Ocean (Takaya et al. 2018). Italian scientists claimed they found evidence of liquid water in a subglacial lake with a diameter of 20 km below the ice of the South Polar Layered Deposits on Mars

(Orosei et al. 2018). For the past decade, the author of this chapter and his research team have been focusing on quantitative prediction and evaluation of mineral resources in the regions covered by transported materials in several provinces of China. Figure 7 shows a successful example of mapping mineral potential for Pb/Zn/Cu and other metals in the Lanping-Jinding area of Yunnan Province. Stream sediment geochemical data (Fig. 7a) were processed using the Spectrum-Area (S-A) fractal filtering method (Cheng 2012a). Use of the S-A method could effectively decompose the weak anomalous from variable background signals (Cheng and Xu 1998; Cheng et al. 2000). The S-A model successfully delineated mineralization-induced anomalies by eliminating

the influence of complex background, especially the interference from the basalt containing high concentration of metals. Five copper-lead-zinc prospecting target areas with equal spatial intervals conforming self-similar distributions have been delineated (Fig. 7b). Based on the above findings, the Geological Survey Institute affiliated to Yunnan Geological Survey carried further exploration and successfully discovered several mineral deposits in the target areas. The same method was further utilized by the Yunnan Geological Survey for mineral prospecting in the entire Sanjiang area and more mineral deposits were discovered in the delineated target areas.

Frontiers of Mathematical Geosciences

Some contributions of mathematical geoscientists to related fields of geosciences have been introduced in the previous section. Next, we will briefly discuss the frontiers of mathematical geosciences, aiming to answer the question are mathematical geoscientists at the earth science frontiers? To answer the question, one approach is to summarize current scientific research in mathematical geosciences, and the other is to study the frontiers of geosciences and the strategic programs of some large international scientific organizations, such as the Future Earth 2025 vision, 2021 Strategic Challenge Domains of ISC, the Resourcing Future Generations (RFG) (Lambert et al. 2013) and Deep-time Digital Earth (DDE) (Cheng et al. 2020) programs led by International Union of Geological Sciences (IUGS), the newly released “Earth in Time, A Vision for NSF Earth Sciences” 2020–2030 by National Academies of Sciences, Engineering and Medicine (2020), US Geological Survey -Century Science Strategy for 2020–2030 (USGS 2021), and the new 2050 Science Framework: Exploring Earth by Scientific Ocean Drilling proposed by the International Ocean Discovery Program (IODP) (Koppers and Coggon 2020). These strategic reports and big science programs have revealed the developing trend of geosciences in next decade from different perspectives. Furthermore, the author has maintained close communication with many international associations through international programs and meetings, including ISC-CSP, IUGG, AGU, EGU, SGA, PDAC, and CGU. Some key topics that can be extracted from above sources of information can reflect the current trends and frontiers of the earth sciences, such as data science, data analysis, computing, interdisciplinary, uncertainty of measurement and prediction, geometry and dynamics of the Earth, climate change and the Arctic, Antarctic, and Tibet Plateau. It also reflects the three major challenges faced by geoscientists in understanding the interaction between the earth system and the human system, understanding the past, present, and future changes of the livable earth’s environment and predicting extreme events on the Earth: (1) The complexity of multilayer interaction of earth system; (2) the chaotic nature of earth processes and the singularity and predictability of extreme earth events; and (3) the effectiveness of observation and monitoring of multi-scale nonlinear mixing processes. These challenges are closely related to mathematical geosciences. Innovations on new mathematical theories, models, and computer software are the prerequisite for dealing with these challenges. Therefore, mathematical geoscientists, confronting great challenges and opportunities, are at the earth science frontiers. Many important progresses have been made by mathematical geoscientists in the earth science frontiers and two examples will be detailed as follows: quantitative simulation of

geocomplexity and applications of big data and artificial intelligence (AI).

Modelling Geocomplexity of the Earth: A New Growing Field of Mathematical Geosciences

Understanding and simulating the complexity and chaotic behaviors of the earth systems is a long-term task for scientists. However, there is no unique scientific definition of complexity of the earth system. Some authors regard modeling geocomplexity as a new kind of science (Wolfarm 2002; Turcotte 2006). These authors emphasize that the geocomplexity refers to nonlinear geological properties that cannot be described or characterized by classical mathematical calculus equations. Simple geological processes can be modeled by means of classical mathematical equations with proper boundary conditions and initial conditions. The temporal and spatial distribution of geological processes can be deterministically predicted, for example, the heat flow at the plate margin over the mid-ocean ridges can be estimated by setting up a diffusion model assuming the plate near the mid-ocean ridge as a regular rigid body, its upper and lower surface temperatures are used as boundary conditions, and the mid-ocean ridge is set as the initial condition. Under several simplifications the analytical or numerical solutions of the established thermal diffusion equation can be derived to estimate the heat flux at any position of the plate. However, many complex geological processes cannot be precisely modeled by the above classical differential equations. For example, it is impossible to precisely describe turbulence by deterministic mathematical model due to statistical uncertainty. In order to study such processes and phenomena, American mathematicians and meteorologists Lorenz (1963) proposed Chaos theory and French American mathematician Mandelbrot (1967) proposed fractal theory in 1960s. For a chaotic system or chaotic process, the output of prediction model behaves very differently if a small disturbance in the initial conditions or boundary conditions. Chaotic systems often appear random and unpredictable, but in fact have regular patterns with scale-invariant properties or fractality (Valentine et al. 2002). Fractal geometry is a new branch of mathematics that describes geometry from the perspective of fractional dimensions, including new geometries between traditional points, lines, surfaces, and volumes (Lovejoy et al. 2009). Fractal geometry is irregular geometry or patterns such as Mandelbrot set and Menger sponge with scale invariant property or self-similarity. Obviously, the concept of fractal geometry has greatly generalized the scope of traditional geometry which provides new effective mathematical tools for studying geocomplexity (Mandelbrot 1967). In recent years, fractal geometry theory and fractal models have been used in almost all disciplines of earth sciences. Just to name a few examples, frequency–size power law models were utilized to

characterize earthquake magnitude-number frequency relationship (Gutenberg and Richter 1944), area-number of plates (Sornette and Pisarenko 2003), plate boundary morphology distribution (Ouillon et al. 1996), magmatic rock area-frequency distribution (Pelletier 1999), volcanic eruption interval distribution (Cannavò and Nunnari 2016), deposit size-number distribution (Agterberg 1995), mineralized alteration zone area-perimeter distribution (Cheng 1995), and geochemical anomalies concentration and area distribution (Cheng 2007b).

With the development of fractal geometry and its application in various fields, the concept of fractal and fractal theory have also been further developed. For example, the proposal of multifractal theory (Mandelbrot 1977) has extended fractals from fractal geometry to self-similar distribution of measures or patterns defined on geometric supports (it can also be fractal geometry) which marks an important leap-forward development of fractal theory (Mandelbrot 1989). Multifractal model can be considered as a new distribution model unifying normal, lognormal, and Pareto distributions. Theory of multifractals provides not only a new way to describe complex spatial patterns with self-similarity but also a basis for further development of fractal calculus and fractal dynamics system (Lovejoy 1991). Since geometric set theory is the foundation of mathematical calculus including integral and differential operations. Only when the mathematical system of geometric measures and calculus operations is established can geometry play a greater role in mathematics. How to build mathematical calculus operations and analysis of other physical quantities related to fractals such as specific gravity, density, and thermal conductivity. Establish calculus based on fractal geometry is a unsolved question which has not been systematically explored in the literature. At the present time, the research progress in this area is still very slow, and more efforts especially by young scholars are encouraged.

The author has been working on the above problems for a long time and first discovered that the concentration values of ore elements in mineralized rocks may follow the multifractal distribution with self-similarity between average concentration levels (density) and areas of mineralized rocks. Further a fractal model (C-A model) was derived to associate the average concentration values and the irregular areas (fractals) delineated with the concentration values around concentration anomalies. This model shows that the concentration (density) of elements on a fractal depicts power law relations between density and area with a negative fractional exponent, implying the concentration within mineralized areas depicts singularity – infinity large of concentration vs infinity small area. The author termed this type of density as “fractal density,” the density defined on fractals or a density with fractal dimension (Fig. 8a). Accordingly proper mathematical model and the local singularity calculation method have been developed to describe fractal density caused by nonlinear

geological processes (earthquakes, mineralization, magmatic events, volcanic events, etc.).

Various extreme events (earthquakes, volcanoes, magmatism, mineralization, tsunamis, landslides, etc.) caused by sudden changes of geological systems were studied to explore their common physical mechanism of formation (Fig. 8b, c) and the singularity of the system outputs. The main types of mechanism that explain most of these extreme events may include but not limited to phase transition mechanisms (supercritical fluid, Moho discontinuity, subduction slab interface, interaction surface between deep magma and surface water, etc.), self-organized criticality (lithospheric delamination, rock fracture, slab fragmentation, etc.), and multiplicative cascading cyclic processes, dissipative structures, and chaotic processes (turbidity current, magma convection, mantle flow, metamorphism, etc.) (Fig. 8b, c) (Cheng 2007b, c, 2008, 2018a).

The author refers to such extreme geological events as singular geological events or events with singularity. The metric fractal density concept and the local singularity analysis (LSA) method developed have been successfully applied to the quantitative simulation and prediction of a variety of extreme geological events (Cheng 2007b). These include the identification of geochemical anomalies caused by concealed ore bodies in the coverage area and the delineation of prospecting target areas (Cheng 2007b, 2015a), seismic probability density-magnitude model (Cheng and Sun 2018), magma flare-up events due to collision of Indian continent and Eurasia continent (Cheng 2018b), anomalous heat flow over the mid-ocean ridges (Cheng 2016), large-scale magma episodic activity and prediction of plates tectonic future evolution (Cheng 2018b, c); and the singularity of lithospheric phase transformation (Cheng 2018a).

Big Data Analytics and Complex Artificial Intelligence

Big data and artificial intelligence (AI) have significantly influenced our life and gradually became research hotspots in many fields of natural science, social science, and economics. However, scientists from different fields may have different opinions about the impact of big data and AI in their research fields. For mathematical geoscientists, they are both the contributors to the development of the data science and the users taking full advantage of big data and AI technology and using them for solving practical problems. One of the good questions for mathematical geoscientists is how to further develop big data analytics and AI technology to enhance the applications.

AI and ML are based on mathematical models, algorithms, and computer performance. Some common ML techniques include linear regression, logistic regression, artificial neural network, naïve Bayes, weights of evidence, random forests, adaBoost, and principal component analysis. Besides, some traditional mathematical methods such as Monte Carlo

Mathematical Geosciences,

Fig. 8 Concepts of fractal density and its mechanisms and possible geological processes that may result in fractal density. **(a)** Normal density and fractal density; **(b)** examples of geological processes that may result in fractal density; and **(c)** mechanisms of fractal density generation. (The figure describing self-organized criticality was adapted from Wiesenfeld et al. 1989)

simulation and least-square fitting are often used in ML. For example, the research algorithm for AlphaGo combined Monte Carlo simulation with value and policy networks (Silver et al. 2016). The abovementioned ML methods are common in mathematical geosciences research. Over the past few decades, these methods have demonstrated great potential for problem solving in mathematical geosciences, particularly for mineral potential mapping and natural resource assessment (Agterberg 1989; Bonham-Carter 1994). In addition, mathematical geoscientists have developed many new models, methods as well as software which have enriched and consummated the function of AI. For example, various variations of the weight of evidence models based on the Bayesian principle have been established ranging from the original

model that requires complete conditional independence of predictors (Naive Bayes, Naïve Bayes, or normal weight of evidence, Weights of Evidence) (Agterberg 1989), to a new model based on predictors with a weak conditional independence (AdaBoost-weight of evidence, AdaBoost Weights of Evidence) (Cheng 2008, 2012b, 2015b) and then to a modified model that does not require conditional independence (weighted weights of evidence) (Journel 2002; Cheng 2008; Zhang et al. 2009; Agterberg 2011).

With the rapid development of deep learning, the research in the field of machine learning using artificial neural network (ANN) models has increased dramatically in recent years. However, even though the current ANN can theoretically approximate all Lebesgue integral function per universal

approximation theorem, it is not capable of approximating complex non-integrable functions at present due to singularity, non-integrability, and non-differentiability. It often needs to set a large number of neurons and more layers (depth) of neurons to approximate complex functions. This of course may increase the number of model parameters, which in turn requires more training data and computational power. Otherwise, the results would be of low stability and even divergent, leading to lower repeatability and precision. How to develop ANN models for solving fractal density related problem caused by singular extreme geological events remains as a question which still requires further investigation. This kind of AI should probably be defined as complex artificial intelligence or local precision artificial intelligence.

Conclusions

Mathematical geosciences is an interdisciplinary science discipline of studying earth characteristics and geological processes, as well as quantitative prediction and evaluation of resources and environment including disasters. Together with other geoscience disciplines MG plays a dispensable role in studying the evolution of the livable earth system, predicting and evaluating various extreme geological events and serving the sustainable development of society. Mathematical geoscientists have made and will continue to make important contributions to the establishment of the modern earth science system and the development of innovative theories and methods to meet the major needs of mankind. Mathematical geoscientists are already at the forefront of earth sciences. It is necessary to publicize the scientific content of mathematical geosciences comprehensively and correctly. It needs to motivate the interest of school and university students in integrating mathematics and geosciences and to encourage and cultivate more young talents to devote them to the MG. Earth science frontiers in the twenty-first century with supports of big data and artificial intelligence require that earth science moves from simple to complex, from local to global, from description to mechanism, from qualitative to quantitative, and from modeling to prediction. Mathematical Geosciences is an emerging discipline full of hope and prospects.

Mathematical Minerals

John H. Doveton

Kansas Geological Survey, University of Kansas, Lawrence, KS, USA

Definition

Mathematical minerals are calculated from chemical or physical measurements as theoretical realizations of actual mineral assemblages in rocks. The concept was first introduced as “normative” minerals in igneous rocks, where oxide analyses were assigned to minerals in a protocol that follows crystallization history. While there is only a general match with observed “modal” minerals, the intent of the procedure is to create hypothetical mineral assemblages which can then be compared between igneous rocks. The concept of normative minerals was extended to sedimentary rocks. However, in this case, the mathematical procedures used attempt to match as closely as possible the volumes of mineral species observed. In the most widely used modern application, mathematical mineral compositions are estimated in subsurface rocks from downhole measurements of physical properties or elements.

Normative Minerals in Igneous Rocks

The Cross-Iddings-Pirsson-Washington (CIPW) norm has been a standard method for many years to transform oxides measured in igneous rocks to theoretical “normative minerals” (Cross et al. 1902). These norms represent hypothetically the minerals that would crystallize if the igneous source was cooled at low pressure under perfect dry equilibrium conditions. The procedure is governed by simplifying assumptions regarding both the order of mineral formation and phase relationships in the melt. These constraints result in a simple model that deviates from the course of naturally occurring igneous mineral differentiation. However, norms are useful for comparison and classification of igneous rocks, particularly for glassy and finely crystalline samples. Normative minerals differ from “modal” minerals observed in the rock, whose volumes are estimated typically from point-counting procedures applied to thin sections.

Normative Minerals in Sedimentary Rocks

As applied to sedimentary rocks, the calculation of normative minerals does not generally follow a genetic model, but simply aims to estimate mineral assemblages that are a close match with those observed. The earliest methods drew on

molecular ratios to calculate the mineral components of a rock, using oxide percentages from analysis (Krumbein and Pettijohn 1938). The suite of minerals to be solved was established from rock sample observation. A stepwise process was then applied to assign the molecular ratios to the mineral set. Unique associations between oxides and certain minerals were resolved first in this procedure, and then the remainder allocated between other components.

Although estimates of standard rock-forming minerals such as quartz or calcite are generally close to volumes observed visually, clay mineral estimation is often problematic when matched with results from X-ray diffraction analysis. The discrepancy is also not surprising because clay-mineral compositions are highly variable, as a result of isomorphous substitution (Imbrie and Poldervaart 1959).

Mineral Compositions Computed from Wireline Petrophysical Logs

The calculation of mineral volumes in the subsurface was originally a byproduct of methods to improve estimates of porosity in multimineral reservoir rocks. Lithologies composed of several minerals required several porosity logs to be run in combination in order to estimate volumetric porosity. In the simplest solution model, the proportions of multiple components together with porosity could be estimated from a set of simultaneous equations for the measured log responses. The earliest application of this technique was in Permian carbonate reservoirs in West Texas where measurements from density, neutron, and sonic logs were used to solve for volumes of dolomite, anhydrite, gypsum, and porosity (Savre 1963).

Compositional analysis by the inverse solution is simple and robust. The unity equation dictates that computed proportions must collectively sum to unity. However, individual proportions can be negative or take values greater than unity. These unreasonable numbers are not caused by estimation error, but simply reflect the location of the sample outside the bounds of the composition space as set by the endmember mineral coordinates. Such results can be used as an informal feedback that may suggest the presence of unaccounted minerals or a need to adjust mineral endmember properties. By the same token, a satisfactory solution does not “prove” a composition, but rather a solution that is consistent with the measurements.

The inversion model can be written as a set of simultaneous equations where the number of knowns and unknowns are matched in a “determined system.” However, when the number of logs is not sufficient for a unique solution, then the result is an underdetermined system. Alternatively, if the number of logs equals or exceeds the number of components, this becomes an overdetermined system. Both

underdetermined and overdetermined systems can be resolved by an expansion of the matrix algebra formulation of the determined system solution (Doveton 1994).

Modern compositional analysis methods have advanced beyond basic inversion models, with the incorporation of tool error functions and constraints as integral components of the solution strategy. In particular, optimal solutions were set with the goal of minimizing the incoherence between log measurements and their values predicted from compositional analysis (Mayer and Sibbit 1980). Not all component log responses need to be estimated since their properties are restricted to a limited range. However, some mineral components have ambiguous properties. The most example of such components are clay minerals, whose composition is widely variable. Calibration to clay minerals in local core is the best practice to reduce estimation uncertainties (Quirein et al. 1986).

Estimation of Minerals in the Subsurface from Geochemical Logging

The use of conventional logs for compositional analysis is implicit in the sense that physical properties are used to deduce mineral proportions. In contrast, elements measured by geochemical logs can be tied directly to mineral compositions. Natural gamma-ray spectroscopy measurements provide potassium, uranium, and thorium while neutron capture spectroscopy supplies silicon, calcium, iron, sulfur, titanium, and the rare earth, gadolinium. While not measured directly, magnesium is generally inferred from the photoelectric factor.

Because there will generally be more minerals than elements to resolve them, the situation is mostly underdetermined. But in reality, most sedimentary rocks are dominated by only ten minerals: quartz, two carbonates, three feldspars, and four clays. Consequently, acceptable compositional solutions can be created with relatively small assemblages of minerals, as long as they have been identified appropriately and that the compositions used are consistent and reasonably accurate (Herron 1988). The solution is aided when some of the elements are associated explicitly with specific minerals. The partition of minerals between species then follows an ordered protocol of assignments. However, the application of simultaneous equations to resolve mineral compositions from elemental measurements provides a more general and effective procedure (Harvey et al. 1990).

As a result of the explicit relations between elemental measures and mineral compositions, much improved mineral transforms have been developed than those of inference from mineral physical properties. The fundamental goal of an effective transform is to provide a close match between normative mineral solutions and modal mineral suites. This aim distinguishes it from the traditional norm of igneous rocks

which is based on hypothetical crystallization and only loosely tied to modal observations (Cross et al. 1902). However, a unique mineral transform from element concentrations may not always be possible in situations of compositional colinearity. If the model is exactly colinear, then there are an infinite range of solutions, creating a matrix singularity and an inversion breakdown (Harvey et al. 1990).

In recent years, methods to resolve subsurface mineralogy estimation have increasingly relied on machine learning algorithms, building on pioneer work that applied simple artificial neural networks (Doveton 2014).

Summary

Mathematical minerals are calculated from chemical or physical measurements of a rock sample as contrasted with actual minerals that are observed. The earliest methods were developed in igneous petrology, where “normative” minerals are computed from oxide analyses, based on a hypothetical and idealized protocol that mimics the order of mineral differentiation. These norms are only a general approximation of “modal” minerals, but are useful for classification purposes. By contrast, normative minerals in sedimentary rocks are computed to be a best match with observed mineral suites. The most common applications today occur in the subsurface, where downhole petrophysical measurements are used to estimate mineralogy by a variety of statistical procedures. The old terminology of “normative minerals” has been mostly replaced by the term of “mathematical minerals.”

Mathematical Morphology

Jean Serra

Centre de morphologie mathématique, Ecoles des Mines,
Paristech, Paris, France

Definition

Mathematical morphology is a discipline of image analysis that was introduced in the mid-1960s. From the very start it included not only theoretical results but also research on the links between geometrical textures and physical properties of the objects under study. Initially conceived as a set theory, with deterministic and random versions, it rapidly developed its concepts in the framework of complete lattices. In geosciences and in image processing, theoretical approaches may rest, or not, on the idea of reversibility. In the first case, addition is the core operation. It leads to convolution, wavelets, Fourier transformation, etc. But the visual universe can be grasped differently, by remarking that the objects are solid and not transparent. An object may cover another, or be included in it, or hit it, or be smaller than it, etc., notions which all refer to set geometry, and which all imply some loss of reversibility. Indeed, the morphological operations, whose core is the order relation, always loose information, and the main issue of the method consists in managing this loss.

Introduction

We will begin by a comment. The petrographic example of Fig. 4 is directly the matter of geosciences. Other ones can easily be transposed. The method for detecting the changes of direction in a piece of oak (Fig. 6) also applies to problems of tectonics, and the way to estimate the roughness of a road

before and after wear (Fig. 7) can serve to quantify the erosion process after an orogeny.

Mathematical morphology, which covers both a theory and a practice, appeared in the middle of the years 1960 with the pioneer works of G. Matheron and J. Serra. They aimed at the description of petrographic structures seen under the microscope (porous media, crystals, alloys, etc.), in order to link them to their physical properties (Matheron and Serra 2002). Objects were considered as sets, that were described either by transforming them (e.g., granulometries), or by modeling them in a probabilistic way (e.g., Boolean closed sets). We present here only the first approach, which extended itself through the years 1970 to numerical functions, under the impulse of medical imaging (Serra 1982). During the years 1980, morphological operations acting on more and more varied objects, the need for unification brought out the concept of *complete lattice* as a common framework (see Serra 1988 in the article “Morphological Filtering”). This algebraic structure lies at the basis of lattice theory, a branch of algebra introduced by the end of the nineteenth century by mathematicians such as E.H. Moore, to whom we owe the crucial notion of a set-theoretical closing, and G. Birkhoff, whose fundamental book has constantly been republished from 1940 until the present time.

Algebraists have much studied the structure of lattices, but have nevertheless given scant attention to the concepts of complete lattice and of lattices of operators: for example in Birkhoff’s book, only one (short) chapter among 17 is devoted to them. Though more recent works written by theoretical computer scientists tackle complete lattices and basic operators such as dilations and openings, nevertheless the idea of describing geometrical features by means of lattices never appears in these studies. The chief notions on which Mathematical Morphology rests, such as morphological filters, segmentation by connections, flat operators, the watershed, levelings, etc., are totally absent from them. In fact, the common logical basis of the lattice has been used in mathematical morphology as starting point for exploring new directions. Since the decade of the 1990s, following the works by H. Heijmans, G. Matheron, Ch. Ronse, and J. Serra, among others (Serra 1988; Heijmans and Ronse 1990; Heijmans 1994; Matheron 1996), the theoretical core of mathematical morphology is developing in an autonomous way. Here we base ourselves on these latter references. A comprehensive bibliography for general morphology is given in Najman and Talbot (2010), and for old mathematical references refer Kiselman (2020) and Ronse and Serra (2010).

Notation: The generic symbol for a complete lattice is $\mathcal{L}$, with some curvilinear variants for the most usual lattices: $\mathcal{P}(E)$ for the family of subsets of the set E , $\mathcal{D}(E)$ for that of partitions of E , $\mathcal{F}$ for the lattice of functions, among others. More generally, curvilinear capital letters designate families of

sets, such as $\mathcal{B}$ for that of invariants of an opening, or a connection $\mathcal{C}$ on $\mathcal{P}(E)$.

Elements of a lattice are generally denoted by lowercase letters; however, we will use capital letters for the elements of the lattices $\mathcal{P}(E)$ and T^E (respectively of parts of E and of numerical functions $E \rightarrow T$), in order to distinguish them from the elements of E (points) or of T (numerical values), denoted by lowercase letters.

Operators acting on lattices are denoted by lowercase Greek letters, of which, in particular, δ , ε , γ , and φ for a dilation, an erosion, an opening, and a closing, respectively. There are some exceptions, for example, **id** for the identity.

Complete Lattices

Partially Ordered Sets

Order relation: Provide the set $\mathcal{L}$ with a binary relation $\leq$ that satisfies the following properties:

$$x \leq x \text{ (reflexivity),}$$

$$x \leq y \text{ and } y \leq x \text{ imply } x = y \text{ (anti-symmetry),}$$

$$x \leq y \text{ and } y \leq z \text{ imply } x \leq z \text{ (transitivity),}$$

for all $x, y, z \in \mathcal{L}$. Then the relation $\leq$ is called a *partial order* and the set $\mathcal{L}$ is *partially ordered* (in short, *p.o.*) by relation $\leq$. The order becomes total when:

$$\forall x, y \in \mathcal{L}, \quad x \leq y \text{ or } y \leq x.$$

Examples (a) The set N of all numbers of the open interval $[0, 1]$ is totally ordered for the usual numerical order. The set of all points of R^d equipped with the relation “ $(x_1, x_2, \dots, x_d) \leq (y_1, y_2, \dots, y_d)$ when $x_i \leq y_i$ for all i ” is partially ordered.

(b) The set $\mathcal{P}(E)$ of all subsets of a set E is partially ordered for the inclusion order $\subseteq$. Let us remark that unlike the set N of the previous example, $\mathcal{P}(E)$ admits a greatest element, E itself, and a least one, namely the empty set $\emptyset$.

Duality: Denote by $(\mathcal{L}, \leq)$ the set $\mathcal{L}$ provided with the order relation $\leq$, and define the relation $\leq^*$ by $x \leq^* y$ if and only if $y \leq x$. This relation $\leq^*$ is an order on $\mathcal{L}$, and $(\mathcal{L}, \leq^*)$ is the *dual* ordered set of $(\mathcal{L}, \leq)$. To each definition, each statement, etc., relative to $(\mathcal{L}, \leq)$, there corresponds a dual notion in $(\mathcal{L}, \geq)$, which is obtained by inverting $\leq$ and $\geq$. This duality principle, which seems to be obvious, plays a fundamental role in mathematical morphology. When an operation has been introduced, it suggests to look also at the dual version, then at the product of both, etc. (for instance: opening and closing).

Complete Lattices

The theory of mathematical morphology rests on the structure of complete lattice. Let $\mathcal{L}$ be a p.o. set, and $\mathcal{K} \subseteq \mathcal{L}$. An element $a \in \mathcal{L}$ is called a *lower bound* of $\mathcal{K}$ if $a \leq x$ for all $x \in \mathcal{K}$, whether a belongs to $\mathcal{K}$ or not. If the family of lower bounds of $\mathcal{K}$ admits a greatest element a_0 , it defines the *infimum* of $\mathcal{K}$. By duality, one introduces the two notions of *upper bound* and *supremum*. The *infimum* (resp., the *supremum*) of a subset $\mathcal{K}$, if it exists, is unique, and is denoted by $\inf \mathcal{K}$ or $\wedge \mathcal{K}$ (resp., $\sup \mathcal{K}$ or $\vee \mathcal{K}$). If $x_i \in \mathcal{L}$ for a (possibly infinite) family I of indexes i , one writes $\wedge_{i \in I} x_i$ for $\wedge \{x_i \mid i \in I\}$, and $\vee_{i \in I} x_i$ for $\vee \{x_i \mid i \in I\}$.

Lattice: A p.o. set $\mathcal{L}$ is a *lattice* when any nonempty finite subset of $\mathcal{L}$ admits an *infimum* and a *supremum*. The lattice is said to be *complete* when this property remains true for all nonempty subsets of $\mathcal{L}$, whether they are finite or not.

By definition, every complete lattice $\mathcal{L}$ has a least element $\mathbf{0} = \wedge \mathcal{L}$ and a greatest element $\mathbf{1} = \vee \mathcal{L}$. These two extreme elements are the *universal bounds* of $\mathcal{L}$. A subset $\mathcal{M}$ of the complete lattice $\mathcal{L}$ constitutes a *complete sublattice* of $\mathcal{L}$ when the *infimum* and the *supremum* of any family in $\mathcal{M}$ belong to $\mathcal{M}$, and when $\mathcal{M}$ contains the universal bounds of $\mathcal{L}$.

Anamorphosis: The term “anamorphosis” appears in painting during the Renaissance, to designate geometrical distortions of figures in the Euclidean plane R^2 that preserve the order of $\mathcal{P}(R^2)$, so that they permit to find back the initial image from its deformation. But this kind of operation appears in many other lattices. So, the map $x \mapsto \log x$, for $x \geq 0$, is an anamorphosis from $\overline{R}_+ \rightarrow \overline{R}$, which extends to numerical functions on E . Formally speaking, it can be defined as follows (Matheron 1996):

Let $\mathcal{L}, \mathcal{M}$ be two complete lattices. A map $\alpha : \mathcal{L} \rightarrow \mathcal{M}$ is an *anamorphosis*, when α is a bijection, and when α and its inverse α^{-1} preserve the order, that is:

$$\forall x, y \in \mathcal{L}, \quad x \leq y \text{ if and only if } \alpha(x) \leq \alpha(y) \quad (1)$$

The most popular morphological operators on gray tone functions are the so-called flat operators, because they commute under anamorphosis.

A map $\mathcal{L} \rightarrow \mathcal{L}$ which coincides with its own inverse ($\alpha^{-1} = \alpha$), like a reflection, is called an *inversion*, or an *involution*, of $\mathcal{L}$.

Remarkable Elements and Families

We now present some remarkable elements or particular subsets that can be found in complete lattices:

Sup-generating family: Let $\mathcal{L}$ be a complete lattice, and $\mathcal{S} \subseteq \mathcal{L}$ a family in $\mathcal{L}$. The class $\mathcal{S}$ is *sup-generating* when every element $a \in \mathcal{L}$ is the *supremum* of the elements of $\mathcal{S}$ smaller than itself:

$$a = \vee \{x \in \mathcal{S} \mid x \leq a\}.$$

Atom: An element $a \neq \mathbf{0}$ of a complete lattice $\mathcal{L}$ is an *atom* when $x \leq a$ implies that $x = \mathbf{0}$ or $x = a$. Any sup-generating family necessarily comprises all the atoms. The lattice $\mathcal{L}$ is *atomistic* when the family of all atoms is sup-generating.

For example, for $\mathcal{L} = \mathcal{P}(E)$, the singletons are atoms, hence the lattice is atomistic.

Co-prime: An element $a \neq \mathbf{0}$ of a complete lattice $\mathcal{L}$ is *co-prime* when $a \leq x \vee y$ implies that $a \leq x$ or $a \leq y$, in a nonexclusive manner. The lattice $\mathcal{L}$ is *co-prime* if the family of its co-primes is sup-generating.

Complement: Let $\mathcal{L}$ be a complete lattice, with universal bounds $\mathbf{0}$ and $\mathbf{1}$. When $x, y \in \mathcal{L}$ are such that $x \wedge y = \mathbf{0}$ and $x \vee y = \mathbf{1}$, they are said to be *complements* of each other. The lattice $\mathcal{L}$ is *complemented* when each of its elements admits at least one complement.

Note that a same element may have several complements. For example, if $\mathcal{L}$ is the lattice of all vector subspaces of R^2 , ordered by inclusion, the complements of a monodimensional subspace are all the other subspaces of dimension 1, whose number is infinite.

Distributivity

Though many properties involve distributivity, this notion is not always simple, because it can be stated at three different levels. Below, we introduce the finite case only. For the two other ones, the reader may refer to Heijmans (1994) and Matheron (1996).

A lattice $\mathcal{L}$ is *distributive* when:

$$\forall x, y, z \in \mathcal{L}, \quad x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z),$$

or equivalently:

$$\forall x, y, z \in \mathcal{L}, \quad x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z).$$

These equalities do not always extend to the case when the collection of those elements inside the first parentheses is infinite.

The notions of distributivity, complementation, atom, and co-prime are closely related (Matheron 1996).

Theorem *In a distributive lattice, the complement of an element, if it exists, is unique and all atoms are co-primes. In a complemented lattice, all co-primes are atoms. Any co-prime complete lattice is infinitely inf-distributive.*

Monotone Convergence and Continuity

Independently of any topology, one can already introduce some convergence and continuity on complete lattices, by relying on their algebraic structure only.

Monotone Limit: Every increasing (resp., decreasing) sequence $x_i (i \in I \subseteq \mathbb{N})$ defines by its *supremum*

(resp. *infimum*) the *sequential monotone limit* $x = \vee_{i \in I} x_i$ (resp. $x = \wedge_{i \in I} x_i$). One then writes $x_i \uparrow x$ (resp. $x_i \downarrow x$). An increasing map $\psi : \mathcal{L} \rightarrow \mathcal{M}$ between the complete lattices $\mathcal{L}$ and $\mathcal{M}$ is $\uparrow$ -continuous when:

$$x_i \uparrow x \text{ in } \mathcal{L} \Rightarrow \psi(x_i) \uparrow \psi(x) \text{ in } \mathcal{M},$$

and $\downarrow$ -continuous when:

$$x_i \downarrow x \text{ in } \mathcal{L} \Rightarrow \psi(x_i) \downarrow \psi(x) \text{ in } \mathcal{M}.$$

The continuity of an Euclidean map is the touchstone of its digitability. In R^2 for example, one can cover any set X by small squares of sides a_i centered at the vertices of a grid, of union X_i . If map ψ is increasing and $\downarrow$ -continuous, then the digital transforms of the X_i tend toward that of the Euclidean set X as $a_i \rightarrow 0$ (Heijmans and Serra 1992; Matheron 1996).

Boolean Lattices

G. Boole modeled the logic of propositions by an algebra with two binary operations, namely disjunction and conjunction, and a unary operation, namely negation, which have the usual property of distributivity. His name was thus given to the corresponding class of lattices:

Boolean Lattice A distributive and complemented lattice, complete or not, is said to be *Boolean*.

In distributive lattices, each element has at most one complement, and in the Boolean case it is unique. This results in the complementation operation on that type of lattice; just as negation in logic, the complementation is an involution:

Theorem Boolean complementation *In a Boolean lattice $\mathcal{L}$, the operation of complementation $x \mapsto x^*$ is an involution of $\mathcal{L}$:*

$$\forall x, y \in \mathcal{L}, \quad x^{**} = x \text{ and } [x \leq y] \Leftrightarrow [x^* \geq y^*].$$

We then have De Morgan's law: for any finite family $x_i (i \in I)$ in $\mathcal{L}$, we have

$$\left(\bigwedge_{i \in I} x_i \right)^* = \bigvee_{i \in I} x_i^* \text{ and } \left(\bigvee_{i \in I} x_i \right)^* = \bigwedge_{i \in I} x_i^*,$$

and when the lattice $\mathcal{L}$ is complete, these two equalities remain valid for the infinite families.

Examples of Lattices

Lattices of Sets

This section is devoted to a few lattices whose elements are subsets of a given arbitrary set E .

Lattices of $\mathcal{P}(E)$ type: The family $\mathcal{P}(E)$ of all subsets of E , ordered by inclusion, constitutes a complete lattice, where the *supremum* and the *infimum* are given by the union and the intersection. This lattice is distributive. Moreover, for all $X \in \mathcal{P}(E)$, the set X^c of those points of E that do not belong to X satisfies the two conditions $X \cap X^c = \emptyset$ and $X \cup X^c = E$; hence X^c turns out to be a complement of X , and it is unique. Therefore $\mathcal{P}(E)$ is Boolean, hence infinitely distributive. The points of E are co-prime atoms, and they form a sup-generating family of $\mathcal{P}(E)$.

One can wonder which ones of all these nice properties suffices to characterize a lattice of $\mathcal{P}(E)$ type. Any finite Boolean lattice is of this type, but it is not always true in the infinite case (see the lattice of the regular closed sets described below). There exist several characterizations of the lattice $\mathcal{P}(E)$, we give here two only.

Theorem *Let $\mathcal{L}$ be a complete lattice. Each of the following two properties is equivalent to the fact that $\mathcal{L}$ is isomorphic to $\mathcal{P}(E)$ for some set E :*

1. $\mathcal{L}$ is co-prime and complemented (Matheron 1996, p. 179).
2. $\mathcal{L}$ is Boolean and atomistic (Heijmans 1994).

Moreover, the set E is uniquely determined (up to an isomorphism): by the co-primes in (1), and by the atoms in (2).

Lattice of convex sets: The set-theoretical lattices are far from being reduced to $\mathcal{P}(E)$ and its sublattices. Here is an example where the order is still the inclusion and the *infimum* the intersection, but where the *supremum* is no longer the union. Remember that a set $X \subseteq R^n$ is *convex* when for all pairs of points $x, y \in X$ the segment $[x, y]$ is contained in X (the definition includes the singletons and the empty set). The class of convex sets is closed under intersection, and partially ordered for inclusion, which induces a complete lattice having the intersection for *infimum*. For the *supremum*, we must consider the intersection of all convex sets that contain $X \subseteq R^2$, that is, its *convex hull* $co(X)$. The *supremum* of the family X_i is then given by the convex hull of their union:

$$\bigvee_{i \in I} X_i = co\left(\bigcup_{i \in I} X_i\right).$$

This lattice is atomistic, but neither complemented, nor distributive.

Lattice of regular closed set: A typical example of Boolean complete lattice is given by the set, ordered by inclusion, of all *regular closed set* of a topological space, namely of

those sets equal to the closure of their interior: $F = \overline{F^\circ}$. The operations of *supremum*, of *infimum*, and of complementation take here the following form:

$$\bigvee_{i \in I} F_i = \overline{\bigcup_{i \in I} F_i} = \left(\bigcup_{i \in I} F_i\right)^\circ, \quad \bigwedge_{i \in I} F_i = \overline{\bigcap_{i \in I} F_i} = \left(\bigcap_{i \in I} F_i\right)^\circ.$$

This complete lattice is Boolean, and we have $\overline{F^c} = (F^\circ)^c$. Regular sets are the only ones which can correctly be approximated by regular grids of points. In geometrical modeling used for image synthesis, objects are represented by regular closed sets, and the Boolean operations on these objects take the above form. For example, in R^3 a closed cube (i.e., that contains its frontier) is a regular closed set, and given two cubes that intersect on a face or on an edge, the *infimum* of the two will be empty, as their intersection has an empty interior.

Lattices of Numerical Functions

Complete chain: One calls a *complete chain* any complete lattice which is totally ordered, as typically the completed Euclidean line $\overline{R} = R \cup \{-\infty, +\infty\}$, or its discrete version $\overline{Z} = Z \cup \{-\infty, +\infty\}$. The sets $\overline{R}_+$ and $\overline{Z}_+$ restrictions of the previous ones to numbers ≥ 0 , are also complete chains. The three chains $\overline{R}$, $\overline{R}_+$, and $\overline{Z}_+$ are isomorphic, but $\overline{Z}$ and $\overline{Z}_+$ are not. In $\overline{R}$ the two operations of numerical *supremum* and *infimum* are continuous for the ordering topology. When the distinction between the various types of complete chains is superfluous, one usually takes the symbol T for representing them in a generic manner.

Lattices $\overline{R}^E$ and $\overline{Z}^E$ of numerical functions: Let E an arbitrary set. Equip the class $\overline{R}^E$ of real functions $F: E \rightarrow \overline{R}$ with the partial order: $F \leq G$ if for all $x \in E$, $F(x) \leq G(x)$. This order induces a complete lattice where the *supremum* and *infimum* are given by:

$$\begin{aligned} G = \bigvee_{i \in I} F_i &\Leftrightarrow \forall x \in E, G(x) = \sup_{i \in I} F_i(x), \\ H = \bigwedge_{i \in I} F_i &\Leftrightarrow \forall x \in E, H(x) = \inf_{i \in I} F_i(x). \end{aligned} \quad (2)$$

This is nothing but a *power* of the lattice $\overline{R}$, that is, a product of lattice $\overline{R}$ by itself $|E|$ times, hence the expression of *power lattice*, and the notation $\overline{R}^E$. The *pulse* functions $u_{x,t}$ defined by:

$$u_{x,t}(y) = t \text{ if } y = x, \quad u_{x,t}(y) = -\infty \text{ if } x \neq y,$$

of parameters $x \in E$ and $t \in R$, are co-primes elements but not atoms, and they constitute a sup-generating family of $\overline{R}^E$; the same notion applies to $\overline{Z}^E$ by taking the pulses $u_{x,t}$ for

$t \in Z$. Both lattices $\overline{R}^E$ and $\overline{Z}^E$ are infinitely distributive, but not complemented.

Note in passing that we must start from the completed line $\overline{R}$, which is a complete chain (or from one of its closed sublattices $\overline{R}_+$, $[0, 1]$, $\overline{Z}$, $\overline{Z}_+$, etc.), and not from the line R , for the latter is not a complete chain. Indeed, equation (2) implies that $G(x)$ might be equal to $+\infty$, or that $H(x)$ might be equal to $-\infty$, even when all $F_i(x)$ are finite.

The lattice $\mathcal{P}(E)$ of sets, ordered by inclusion, is isomorphic to lattice 2^E of all binary functions $E \rightarrow \{0, 1\}$, equipped with the numerical ordering.

Lattices of the Lipschitz functions: The class of all numerical functions is too comprehensive for modeling images of the physical world, and has too many pathological cases unsuitable for discrete approximations. On the other hand, the class of all continuous functions does not form a complete lattice: for example, the functions x^n , $n \geq 0$, taken between 0 and 1 are continuous, whereas $y = \bigwedge_n \geq 0 x^n$ is not. The upper (or lower) semi-continuous functions on R^n do form a lattice, but it is not closed under subtraction, and its *supremum*, namely the topological closure of the usual supremum, is not pointwise. In addition, these functions, which may have no minimum, are inadequate candidates for operations such as the watershed, for example. We must find something else.

When the starting space E is metric of distance d , the functions $F : E \rightarrow \overline{R}$ that are the most convenient for morphological operators are undoubtedly the Lipschitz functions, or their extensions under anamorphoses. The Lipschitz functions of module ω satisfy the inequality:

$$\forall x, y \in E, |F(x) - F(y)| \leq \omega \times d, \quad (3)$$

The class $\mathcal{F}_\omega$ of these functions has three basic properties; for every module ω :

1. The constant functions belong to $\mathcal{F}_\omega$
2. $a \in R$ and $F \in \mathcal{F}_\omega$ imply that $a + F \in \mathcal{F}_\omega$
3. $F \in \mathcal{F}_\omega$ implies that $-F \in \mathcal{F}_\omega$

Conversely (Matheron 1996), every complete sublattice $\mathcal{L}$ of $\overline{R}^E$ satisfying these three properties and $\sup_{F \in \mathcal{L}} |F(y) - F(x)| < +\infty$ for all $x, y \in E$, must be Lipschitz for some metric on E .

When we state the incredible series of properties that the $\mathcal{F}_\omega$ do satisfy, one wonders by which miracle they fit so well with the morphological requirements (Serra 1992; Matheron 1996):

1. If function $F \in \mathcal{F}_\omega$ is finite at one point $x \in E$, then it is finite everywhere.

2. For each module ω , the $\mathcal{F}_\omega$ functions form a complete sublattice of the lattice $\overline{R}^E$ of all numerical functions on $\overline{R}$, hence with pointwise sup and inf.
3. Each $\mathcal{F}_\omega$ is a compact space for both topologies of pointwise convergence, and of uniform convergence, identical here.
4. When the space E is affine, each lattice $\mathcal{F}_\omega$ is closed under any (non-necessarily flat) dilation or erosion which is invariant under translation, and these operations are continuous. For example, if $E = Z^n$ or R^n , and if B stands for the unit ball, then for $F \in \mathcal{F}_\omega$, *Beucher's gradient* $\frac{1}{2}[(F \oplus B) - (F \ominus B)] \in \mathcal{F}_\omega$.
5. If $\{K(x) | x \in E\}$ is a family of variable compact structuring elements, whose Hausdorff distance h satisfies the inequality $h[K(x), K(y)] \leq d(x, y)$, then $\mathcal{F}_\omega$ is closed under flat dilation and erosion according to the $K(x)$, and these operations are continuous.
6. The two above properties extend to *suprema*, to *infima*, and to finite composition products of dilation and erosion.
7. If $g(dy)$ is a measure such that $\int_E |g(dy)| \leq 1$, then the lattice $\mathcal{F}_\omega$ is closed under convolution by g , and this operation is continuous.
8. When E and $\overline{R}$ are sampled by means of regular grids, then the previous operations can be arbitrarily approximated by their digital versions (a consequence of the continuities).
9. Since each $\mathcal{F}_\omega$ is a compact space, one can define probabilities on it, and generalize the theory of the random sets.
10. The finite products of lattices $\mathcal{F}_\omega$ still satisfy all above properties (e.g., multispectral images).

Lattice of Partitions

Now here is a lattice whose objects are no longer sets of points, or numerical functions, but cuttings of space.

Definition Partition *Let E be an arbitrary space. A partition of E is a family $\mathbf{P}$ of subsets of E , called classes, which are:*

1. *Non-empty:* $\emptyset \notin \mathbf{P}$
2. *Mutually disjoint:* $\forall X, Y \in \mathbf{P}, X \neq Y \Rightarrow X \cap Y = \emptyset$
3. *Whose union covers E :* $\bigcup \mathbf{P} = E$

Equivalently, the partition corresponds to a map $D : E \rightarrow \mathcal{P}(E)$ that satisfies the following two conditions:

- for all $x \in E, x \in D(x)$
- for all $x, y \in E, D(x) \cap D(y) \neq \emptyset \Rightarrow D(x) = D(y)$

$D(x)$ is called the *class* of the partition in x .

Partitions intervene in *image segmentation* (see article “*Morphological Filtering*”). To segment a graytone or color image, one partitions its space of definition into zones which are homogeneous in some sense. Therefore, it should be useful to handle these partitions just as we do with sets or with functions.

The set $\mathcal{D}(E)$ of partitions of E is partially ordered by *refinement*: we say that partition D_f is *finer* than partition D_g , or that D_g is *coarser* than D_f , and we write $D_f \leq D_g$, when each class of D_f is included in a class of D_g :

$$D_f \leq D_g \Leftrightarrow \forall x \in E, D_f(x) \subseteq D_g(x).$$

The set $\mathcal{D}(E)$, provided with this order is a complete lattice; the greatest element (the coarsest partition) is the *universal partition* D_1 whose unique class is E , whereas the least element (the finest partition) is the *identity partition* D_0 whose classes are all singletons:

$$\forall x \in E, D_1(x) = E \text{ and } D_0(x) = \{x\}.$$

The class at point x of the *infimum* of a family $\{D_i | i \in I\}$ of partitions is nothing but the intersection of the classes $D_i(x)$:

$$\forall x \in E, \left[\bigwedge_{i \in I} D_i \right](x) = \bigcap_{i \in I} D_i(x).$$

The *supremum* of partitions $D_i (i \in I)$ is less straightforward. Formally, it is the finest partition D such that $D_i(x) \subseteq D(x)$ for all $i \in I$ and $x \in E$, see Fig. 1.

The lattice $\mathcal{D}(E)$ of partitions of E is not distributive. However, it is complemented and atomistic, the atoms being those partitions where exactly one class is a pair $\{x_1, x_2\}$, all other classes being singletons.

Lattices of Operators

We just modeled objects and cuttings. But we can as well represent as lattices most of the families of morphological operations, which is a major achievement of Mathematical Morphology. In the set-theoretical case, for example, the family $\mathcal{A}$ of all maps from $\mathcal{P}(E)$ into itself is ordered by the following relation between elements α, β of $\mathcal{A}$:

$$\alpha \leq \beta \Leftrightarrow \forall X \in \mathcal{P}(E), \alpha(X) \subseteq \beta(X).$$

This induces the following complete lattice with obvious *supremum*:

$$\alpha = \bigvee_{i \in I} \alpha_i \Leftrightarrow \forall X \in \mathcal{P}(E), \alpha(X) = \bigcup_{i \in I} \alpha_i(X),$$

Mathematical Morphology, Fig. 1 Supremum of two partitions

and *simili modo* for the *infimum*. The universal bounds are the constant operators $X \mapsto E$ and $X \mapsto \emptyset$. The lattice $\mathcal{A}$ is indeed $\mathcal{P}(E)$ at power $\mathcal{P}(E)$; it is therefore Boolean and atomistic.

Duality by complementation: A new duality appears here, different from that induced by the order. As $\mathcal{P}(E)$ is complemented, we can associate with any element $\alpha \in \mathcal{A}$ its *dual* α^* for the complementation by means of the relation

$$\forall X \in \mathcal{P}(E), \alpha^*(X) = [\alpha(X^c)]^c. \quad (4)$$

Operator α^* has all properties dual (in the sense of the order) of those of α ; in particular

$$\alpha_1 \leq \alpha_2 \Leftrightarrow \alpha_1^* \geq \alpha_2^*, \quad \left[\bigvee_{i \in I} \alpha_i \right]^* = \bigwedge_{i \in I} [\alpha_i^*].$$

Note that $(\alpha^*)^* = \alpha$, that is, an operator is the dual of its dual.

We can now generalize and consider the set $\mathcal{O}$ of all operators $\mathcal{L} \rightarrow \mathcal{L}$ for an arbitrary complete lattice $\mathcal{L}$. This set is ordered like $\mathcal{A}$ and has a similar structure of complete lattice. We are thus able to consider operators having the various properties defined below (increasingness, extensivity, closing, etc.) on classes of objects, for example, functions and partitions, as soon as the latter are themselves structured in complete lattices.

Many lattices are not isomorphic to their dual in the sense of the order, and therefore do not admit an inversion, for example: the lattice of convex sets, that of partitions, etc. It means that the duality by complementation cannot be extended to this type of lattice. In practice, in these lattices,

dual operations, for example, opening and closing, will look very dissimilar.

Duality by inversion: In the lattices of numerical functions $E \rightarrow \bar{R}$, for each real constant t , the map $N : \bar{R}^E \rightarrow \bar{R}^E : F \mapsto t - F$ is an inversion. The same applies if we take the interval $[a, b]$ instead of $\bar{R}$, provided that we put $t = a + b$. That allows us to establish a duality similar to equation (4). For any operator $\beta : \bar{R}^E \rightarrow \bar{R}^E$, the dual β^* defined by:

$$\beta^*(F) = N(\beta(N(F))) \quad (5)$$

plays a role similar to α^* in the set-theoretical case.

Increasing operator: An operator $\alpha \in O$ is *increasing* when:

$$\forall x, y \in \mathcal{L}, \quad x \leq y \quad \Rightarrow \quad \alpha(x) \leq \alpha(y).$$

The glasses of a myopic person are a typically increasing. We easily see that the increasing operators form a complete lattice O' , a complete sublattice of O .

Extensive and anti-extensive operator: An operator $\alpha \in O$ is *extensive* (resp., *anti-extensive*) when for all $x \in \mathcal{L}$ we have $x \leq \alpha(x)$ (resp., $x \geq \alpha(x)$). Both families of extensive operators and of anti-extensive ones are closed under *non-empty supremum* and *infimum*, but they do not form complete sublattices of O because they do not admit the same universal bounds. For example, the least extensive operator is the identity $\text{id} : x \mapsto x$ whereas the least element of O is the operator $x \mapsto 0$;

Idempotent operator: An operator $\alpha \in O$ is *idempotent* if $\alpha^2 = \alpha$, that is, when

$$x \in \mathcal{L} \quad \alpha(\alpha(x)) = \alpha(x)$$

Idempotence occurs everywhere in physics and in geosciences, and it also appears in the daily life at all times. To look through a yellow glass (supposed to be bandpass), to empty a bottle, to be born, to die are all idempotent operations. One understands why idempotence, associated with increasingness, is at the root of morphological filtering.

One can also consider the complete lattice of operators $\alpha : \mathcal{L} \rightarrow \mathcal{M}$, where $\mathcal{L}$ and $\mathcal{M}$ are two distinct complete lattices; for example, $\mathcal{L} = T^E$ and $\mathcal{M} = \mathcal{P}(E)$, and α is a binarization. Then some notions keep their meaning (e.g., increasingness), other lose it (e.g., (anti-) extensivity, idempotence). Note that the product $\alpha\beta$ supposes that the starting lattice of α coincides with the arrival lattice of β .

Closings and Openings

Openings and closings are at the basis of morphological filtering of images (see the article “Morphological filtering”).

They are also the easiest operators to characterize. We shall thus describe them in the first place.

Closings in complete lattices had already been studied by algebraist mathematicians since the years 1940, like R. Baer, C. Everett, and O. Ore. These works form the basis of the theory developed subsequently in mathematical morphology.

Moore Families and Closings

In mathematics, one encounters numerous examples of objects closed under one operation. For example, a set X in Euclidean space is convex if it is closed under the operation joining any two points by a segment. If the set is not closed, one defines then its closing as the least closed set containing it, namely its convex hull $C(X)$. Remark that $X \subseteq C(X)$, that for any two sets $X, Y \in R^2$ if $X \subseteq Y$, then $C(X) \subseteq C(Y)$, and finally that $C(X) = C[C(X)]$. The convex hull operation is thus extensive, increasing, and idempotent.

As seen by E. Moore in 1910, the two notions of “closed set” and of “closing” correspond to each other: a closed object is the closing of an object, while the closing of an object is the least closed object containing it. This assumes that among all closed objects containing a given object, there exists one that is the least one. In other words, the lattice structure is perfectly well-suited here.

Definition Let $\mathcal{L}$ be a complete lattice, whose least and greatest elements are 0 and 1 .

1. A closing on $\mathcal{L}$ is an operator φ on $\mathcal{L}$ that is extensive, increasing, and idempotent.
2. The invariance domain of an operator ψ on $\mathcal{L}$ is the set

$$\mathcal{B}_\psi = \{x \in \mathcal{L} \mid \psi(x) = x\}.$$

3. A part $\mathcal{M}$ of $\mathcal{L}$ is a Moore family when $\mathcal{M}$ is closed under the operation of infimum and includes 1 .

In fact, the notions of Moore family and of closing represent the same thing under two different angles:

Theorem Closings and Moore families There is a one-to-one correspondence between Moore families in $\mathcal{L}$ and closings on $\mathcal{L}$:

- To a Moore family $\mathcal{M}$ one associates the closing φ defined by setting for every $x \in \mathcal{L}$: $\varphi(x)$ is the least $y \in \mathcal{M}$ such that $y \geq x$.
- To a closing φ one associates the Moore family defined by its invariance domain $\mathcal{B}_\varphi = \{\varphi(x) \mid x \in \mathcal{L}\}$.

Openings

One can take the dual point of view, by inverting the order and transposing *supremum* and *infimum*. The previous definitions and theorems become thus the following statements:

1. One calls an opening on $\mathcal{L}$ an operator γ that is anti-extensive, increasing, and idempotent.
2. One calls a dual Moore family of $\mathcal{L}$ a part $\mathcal{M}$ closed under the operation of supremum and includes $\mathbf{0}$,

As previously, here is a one-to-one correspondence between dual Moore families in $\mathcal{L}$ and openings on $\mathcal{L}$:

- To a dual Moore family $\mathcal{M}$ one associates the opening γ defined by setting for every $x \in \mathcal{L}$: $\gamma(x)$ is the greatest $y \in \mathcal{M}$ such that $y \leq x$.
- To an opening γ one associates its invariance domain $\mathcal{B}_\gamma = \{\gamma(x) | x \in \mathcal{L}\}$ which is a dual Moore family.

Generation of Closings and Openings

One can construct openings and closings by using their structures.

Theorem Structural theorem of openings Let $\mathcal{L}$ be a complete lattice and $\mathcal{L}'$ be the lattice of the increasing operations on $\mathcal{L}$. The set of all openings on $\mathcal{L}$ is closed under the supremum in $\mathcal{L}'$. For any family $\{\gamma_i\}$ of openings, the supremum $\vee_{i \in I} \gamma_i$ is itself an opening. The least opening is the constant operator $x \mapsto \mathbf{0}$, the greatest one is the identity **id**. (dual statements for the closings).

Remark, however, that neither the product $\gamma_1 \gamma_2$ of two openings nor the infimum $\wedge_{i \in I} \gamma_i$ openings are openings. The structural theorem orients us towards the construction of openings by suprema of a few basic ones. In practice indeed, all openings derive from two ones, namely the opening by adjunction defined by Eq. (6) and the connection opening defined by Eq. (2) of the article “Morphological Filtering.”

Dilation and Erosion

Minkowski Operations

In the same way as closings and openings, dilations and erosions represent a pair of fundamental notions in mathematical morphology. Their correspondence is intimately linked to that of *Galois correspondence*, which had already been studied by mathematicians under the name of *adjunction*.

However, the algebraists have not given attention to the properties of lattices that derive from Euclidean space, such as invariance under translation, convexity, and similarity, and missed completely the Minkowski operations. In fact, it is to the school of integral geometry, which knew nothing about lattices, that one owes the primary adjunction of mathematical morphology. In 1903, Minkowski defined the addition of two Euclidean sets by the relation:

$$X \oplus B = \{b + x, x \in X | b \in B\} = \bigcup_{x \in X} B_x = \bigcup_{b \in B} X_b.$$

where B_x (resp. X_b) indicates the translate of B at point x (resp. X at point x). When one fixes B , the operator $\delta_B : X \mapsto X \oplus B$, is a dilation, in the sense that it commutes with the union, and provides even the general form of dilations invariant under translation in $\mathcal{P}(E)$, where $E = \mathbb{R}^n$ or $\mathbb{Z}^n$. The adjoint erosion:

$$\varepsilon_B : X \mapsto X \ominus B = \bigcap_{b \in \check{B}} X_b,$$

where $\check{B} = \{-b | b \in B\}$ is the reflected set of B , is named the Minkowski subtraction, although he himself did not envisage it. It appeared with Hadwiger in 1957, who nevertheless did not envisage, himself, the opening by adjunction.

The eroded $X \ominus B$ is the locus of those points x that B_x is included in X , and the dilate $X \oplus B$ is the locus of those points x that $\check{B}_x$ hits set X (the geological term of “erosion” obviously has another meaning). In the set case, most of the structuring elements met in practice, like the segment, the square, the hexagon, the disc, the sphere, are symmetrical, that is, $\check{B} = B$ and the small hat can just be omitted. Figure 2 (left and center), illustrates two usual Minkowski operations. Note that the erosion by the disk centered about the origin o is anti-extensive, but not that by the pair of points, that does not contain o .

Figure 2 (right) introduces another type of dilation, namely by geodesic disks (Lantuéjoul and Beucher 1981). We present it in the digital case. Consider a digital metric on $\mathbb{Z}^n$, and let $\delta(x)$ stands for the unit ball centered at point x , then the unit geodesic dilation of set Y inside set X is defined by the relation:

$$\delta_X(Y) = \delta(Y) \cap X$$

The dilation of size n of Y inside X is then obtained by iteration:

$$\delta_{X,n}(Y) = \delta(\dots \delta(\delta_X(Y)) \cap X \dots) \cap X \quad n \text{ times}$$

Unlike the Minkowski addition, it is not invariant under translation of Y when the background X is fixed. For n large enough, and if we assumed that set X is regular and bounded,

Mathematical Morphology, Fig. 2 Left: Minkowski addition and subtraction by a disk (the initial cat is the median gray image); center: erosion by a pair of points equidistant from the origin; right: in gray, geodesic dilation of the white spot for the hexagonal metric

the geodesic dilation of point p , considered as a marker, completely invades the connected component of X hit by p .

$$\bigvee_n \delta_{X,n}(X) = \gamma_p(X) \quad (6)$$

The operator γ_p is therefore called the *connection opening at point p* , and is studied in the article “Morphological Filtering.”

It is Matheron (1967) who introduced, in view of granulometries, the opening by adjunction:

$$\gamma_B = \gamma_B \varepsilon_B : X \mapsto (X \ominus B) \oplus B \quad (7)$$

by a structuring element B . The open set $\gamma_B(X)$ is the union of those sets B_x that are included in X . The corresponding Moore family is the invariance domain $\mathcal{B}_\gamma$ of γ_B , which consists of all unions of translates of B . The closing dual for complementation is:

$$\varphi_{\check{B}} = \varepsilon_{\check{B}} \delta_{\check{B}} : X \mapsto (X \oplus \check{B}) \ominus \check{B}.$$

The notations δ_B , ε_B , γ_B , and φ_B mean that one lies in R^n or Z^n and that the operators, with structuring element B , are invariant under translation. For linking openings and granulometries, Matheron bases himself on the following theorem (Matheron, 1975):

Theorem *A family $\{B_\lambda \mid \lambda \geq 0\}$ constitutes the continuous additive semi-group:*

$$B \oplus B_\mu = B_{\lambda+\mu}, \lambda, \mu \geq 0$$

if and only if each B_λ is homothetic with ratio λ of a convex compact B .

In the structure of mathematical morphology, this theorem plays the role of a corner-stone, which distributes the

load in various directions. It leads on the one hand to granulometries, but opens also the door to partial differential equations (Maragos 1996), and finally permits to decompose convex structuring elements for implementing the easily. In particular, any family $\{\gamma_{\lambda B} \mid \lambda \geq 0\}$ of openings by homothetic convex sets turns out to be a granulometry. Figure 3 depicts a granulometry of the black phase by discs, or equivalently increasing closings of the whites.

An Example

In a blast furnace, chemical reductions of the initial pellets of sinters (magnetite or hematite) result in iron, according sequences of the type

The reductions are obtained by circulation of CO through the pores. However, these overall relations do not tell us how the process occurs (Jeulin 2000). Is the whole hematite pellet transformed into a whole pellet of ferrite, and then into iron?

In Fig. 4, the reduction process is caught red-handed. It is a polished section taken from the middle of the blast furnace. The three phases are imbricated. Is the ferrite phase relatively closed to hematite, or not?

A convenient tool for answering the question, here, is the rectangular covariance $C_{ij}(h)$. Take a structuring element made of two points from h apart in the horizontal direction, $C_{ij}(h)$ is the proportion of cases when the left point falls in phase i and the right one in phase j (Fig. 5).

The slope of covariance near the origin is proportional to the contact surface per unit volume. The two ferrite covariances are similar. Unlike, that between hematite and pores starts from more below, which means smaller contact surface. Moreover it presents a hole effect for $h = 50$ this indicates a halo of ferrite around hematite.

Mathematical Morphology, Fig. 3 Initial set, and closings φ_B (center) and $\varphi_{B'}$ (right) with B and B' discs, and $B \subseteq B'$

Mathematical Morphology, Fig. 4 Light gray: hematite; dark gray: ferrite; black: pores

Dilations and Erosions, Adjunctions

The generalization of the Minkowski operations, and of their links, is straightforward:

Definition. Dilation, Erosion, and Djunction Let $\mathcal{L}$ and $\mathcal{M}$ be two complete lattices (identical or distinct).

1. An operator $\delta : \mathcal{L} \rightarrow \mathcal{M}$ is a dilation when it preserves the supremum:

$$\forall \{x_i | i \in I\} \subseteq \mathcal{L}, \quad \varepsilon \left(\bigwedge_{i \in I} x_i \right) = \bigwedge_{i \in I} \varepsilon(x_i);$$

Mathematical Morphology, Fig. 5 The three rectangle covariances of the sinter specimen

in particular, for I empty, $\varepsilon(\mathbf{1}) = \mathbf{1}$.

3. Two operators $\delta : \mathcal{L} \rightarrow \mathcal{M}$ and $\varepsilon : \mathcal{M} \rightarrow \mathcal{L}$ form an adjunction (ε, δ) when:

$$\forall x \in \mathcal{L}, \forall y \in \mathcal{M}, \quad \delta(x) \leq y \Leftrightarrow x \leq \varepsilon(y). \quad (8)$$

Dilation and erosion are dual notions. It is easy to see that both are *increasing operators*. Conversely, every increasing operator preserving $\mathbf{0}$ (respectively, preserving $\mathbf{1}$) is an *infimum* (respectively, a *supremum*) of dilations (respectively, erosions) (Serra 1988).

Theorem Adjunctions. Let $\mathcal{L}$ and $\mathcal{M}$ be two complete lattices. Adjunctions constitute a bijection between dilations $\mathcal{L} \rightarrow \mathcal{M}$ and erosions $\mathcal{M} \rightarrow \mathcal{L}$, that is:

1. Given two operators $\delta : \mathcal{L} \rightarrow \mathcal{M}$ and $\varepsilon : \mathcal{M} \rightarrow \mathcal{L}$ forming an adjunction (ε, δ) , δ is a dilation and ε is an erosion.
2. For every dilation $\delta : \mathcal{L} \rightarrow \mathcal{M}$, (resp. erosion ε) there exists a unique erosion $\varepsilon : \mathcal{M} \rightarrow \mathcal{L}$ (resp. dilation δ) such that (ε, δ) is an adjunction.

Composing the erosion and the dilation by a structuring element, one obtains according to the order of composition the opening γ and the closing φ by that structuring element. That remains true in the general case.

Theorem Opening and closing by adjunction Let $\mathcal{L}$ and $\mathcal{M}$ be two complete lattices, and let a dilation $\delta : \mathcal{L} \rightarrow \mathcal{M}$ and an erosion $\varepsilon : \mathcal{M} \rightarrow \mathcal{L}$ form an adjunction (ε, δ) . Then:

1. $\varepsilon = \varepsilon\delta\varepsilon$ and $\delta = \delta\varepsilon\delta$.
2. $\delta\varepsilon$ is an opening on $\mathcal{M}$ whose invariant elements are the dilates of the initial elements $\mathcal{B}_{\delta\varepsilon} = \delta(\mathcal{L})$.
3. $\varepsilon\delta$ is a closing on $\mathcal{L}$ and $\mathcal{B}_{\varepsilon\delta} = \varepsilon(\mathcal{M})$.

The two lattices $\mathcal{L}$ and $\mathcal{M}$ often are identical, and $\delta, \varepsilon, \delta\varepsilon$, and $\varepsilon\delta$ are just operators on $\mathcal{L}$.

General Set-Theoretical Case

Let us illustrate these notions in the case of lattices of the form $\mathcal{P}(E)$. According to the definition of dilation and erosion, an operator is a dilation if it preserves the union, and an erosion if it preserves the intersection. One can characterize a dilation by its behavior on the points identified to singletons; for every point p , let us write $\delta(p)$ for $\delta(\{p\})$. Then:

Theorem Let E_1 and E_2 be two spaces. A map $\delta : \mathcal{P}(E_1) \rightarrow \mathcal{P}(E_2)$ is a dilation if and only if:

$$\forall X \in \mathcal{P}(E_1), \quad \delta(X) = \bigcup_{x \in X} \delta(x). \quad (9)$$

The adjoint erosion $\varepsilon : \mathcal{P}(E_2) \rightarrow \mathcal{P}(E_1)$ is then given by:

$$\forall Y \in \mathcal{P}(E_2), \quad \varepsilon(Y) = \{x \in E_1 \mid \delta(x) \subseteq Y\}. \quad (10)$$

In the case where $E_1 = E_2 = E = \mathbb{Z}^n$ or $\mathbb{R}^n$, one easily sees by equation (9) that every dilation invariant under translation is of the form $\delta_B : X \mapsto X \oplus B$, with the structuring element $B = \delta(o)$, the dilation of the origin. An erosion is invariant under translation if and only if the adjointed dilation is invariant under translation, hence it will be of the form $\varepsilon_B : X \mapsto X \ominus B$. The dilation δ_B is increasing in B , but ε_B is decreasing in B . Moreover, one has:

$$\bigvee_{i \in I} \delta_{B_i} = \delta_{\bigcup_{i \in I} B_i} \quad \text{and} \quad \bigwedge_{i \in I} \varepsilon_{B_i} = \varepsilon_{\bigcup_{i \in I} B_i}.$$

The rules of compositions of dilations and erosions derive from these relations, which imply:

$$\delta_{B_1} \delta_{B_2} = \delta_{B_2} \delta_{B_1} = \delta_{B_1 \oplus B_2}$$

$$\varepsilon_{B_1} \varepsilon_{B_2} = \varepsilon_{B_2} \varepsilon_{B_1} = \varepsilon_{B_1 \oplus B_2}$$

The opening $\gamma_B = \delta_B \varepsilon_B$ admits for invariant sets the dilated by B , that is, the $A \oplus B$ for $A \in \mathcal{P}(E)$. Similarly, the invariance domain of the closing $\varphi_B = \varepsilon_B \delta_B$ is formed of sets eroded by B , that is, the $A \ominus B$ pour $A \in \mathcal{P}(E)$.

We conclude this section by a more general result: every opening invariant under translation, in $\mathbb{R}^n$ or $\mathbb{Z}^n$, can be written as a supremum of openings of the type γ_B (Matheron 1975), and more generally, every opening in a complete lattice expresses itself under the form of a supremum of openings by adjunction (Heijmans and Ronse 1990).

Case of the Unit Circle

Morphological operations on the unit circle appear in color images processing, where the hue spans the unit circle. We will not develop morphology for color images here, and refer to Angulo (2007). Another field of applications is the processing of directions, more useful in geosciences. We give below a few indications in the 2-D case of the unit disc C . The approach extends to the unit sphere, but the formalism is less simple.

The unit disc C , like the round table of King Arthur knights, has no order of importance, and no dominant position. This signifies we cannot construct a lattice on it, unless the phenomenon under study imposes its origin. However, there are three paths to bypass this interdiction, by focusing on *increments*, a wide class which covers residues, gradients, medians, etc. (Hanbury and Serra 2001).

The points a_i on the unit disc C of center O are indicated by their angle, between 0 and 2π from an arbitrary origin a_0 . Given two points a and a' , we use the notation $a \div a'$ to indicate the value of the acute angle $a\widehat{O}a'$, that is,

$$\begin{aligned} a \div a' &= |a - a'| & \text{if } |a - a'| \leq \pi \\ a \div a' &= 2\pi - |a - a'| & \text{if } |a - a'| \geq \pi \end{aligned}$$

Now consider the opening by adjunction $\gamma_B(f)$ of function f by B , and indicate by $\{B_i, i \in I\}$ the family of structuring elements which contain point x . The residue at point x can be written

$$f(x) - \gamma_B(f)(x) = -\sup_{i \in I} \left\{ \inf_{y \in B_i} [f(y) - f(x)] \right\},$$

in which there are only increments of the function f around point x . This general relation can be transposed to circular values a and gives

$$f(x) - \gamma_B(f)(x) = -\sup_{i \in I} \left\{ \inf_{y \in B_i} [a(x) \div a(y)] \right\}.$$

Gradients and medians on the unit disc are obtained in the same manner.

An Example

When sorting oak boards destined to make furniture, it is necessary to find the knots, which appear as fast changes of direction, and to measure the sizes. The average direction of the veins is calculated over small squares, and the residues of circular openings on these directions indicate the knots. Figure 6 depicts the residues found onto the original image, for the four sizes 3, 5, 7, and 9 of the structuring element.

Case of Numerical Functions

Let $T = \bar{R}, \bar{Z}$ or a closed interval of $\bar{R}$ or $\bar{Z}$ and $E = R^n$ or $E = Z^n$. A numerical function $E \rightarrow T$ is equivalent to its *subgraph*, or *umbra* in the product space $E \times T$ (Sternberg, 1986), that is to the set of all points (x, t) which are below $(x, F(x))$, and dilating the umbra of function F by that of function G still results into an umbra, which in turn defines

the dilated function $\delta_G(F)$. In the translation invariant case the formalism is as follows:

$$\begin{aligned} \delta(F \oplus G)(x) &= \bigvee_{y \in E} [F(x - y) + G(y)], \\ \varepsilon(F \ominus G)(x) &= \bigwedge_{y \in E} [F(x + y) - G(y)] \end{aligned} \quad (11)$$

An Example

This example concerns the wear of road surface. Under the traffic, the bitumen of a road loses its initial roughness quality, and one wishes to measure this phenomenon (Serra 1984). A ring of 20 m emulates the road, and a massive set of four wheels emulates the truck. Two experiments, of 1.000 and then 10.000 passages of 6.5 t trucks going at 65 km/h, are made. The relief of the road is measured afterwards by a sensor which produces the two plots of Fig. 7 (left).

The set under the plot is eroded by a segment of length l and direction α , and the area reduction is averaged in α . This result in the function $P(l)$ whose second derivative $f(l)$ is the histogram of the intercepts. It admits the following limited expansion near the origin:

$$f(l) = \frac{a}{E(C)} l$$

Mathematical Morphology, Fig. 6 Detection of knots in an oak board as changes in direction

Mathematical Morphology, Fig. 7 Left: changes in the roughness of a road surface; right: beginnings of the histograms of the road intercepts

where a is a constant and C stands for the average of the average curvature, assuming that the road relief admits curvatures. By measuring $f(h)$ in six directions and applying the above formula, we find: $E(C) = 2210^{-2}\text{mm}^{-2}$ before wear and $E(C2) = 10^{-2}\text{mm}^{-2}$ after wear (Fig. 7 (right)). In spite of the curvatures assumption, of the poor number of directions, and the passage to a second derivation, the model still provides a pertinent information. Remark the stereological meaning of the result: by means of 1-D structuring elements one reaches, by rotation averaging, an estimate of the 3-D average curvature.

Flat Structuring Elements

The most popular numerical dilations and erosions are those obtained by level set approach, where each thresholded set is treated individually. This amounts to use “flat” structuring functions, that is, to take for G the half cylinder:

$$x \in B \Rightarrow G_B(x) = 0 \quad x \notin B \Rightarrow G_B(x) = -\infty$$

The relations (Eq. 11) of numerical dilation and erosion take the simpler form:

$$\begin{aligned} \delta(F \oplus G)(x) &= \bigvee_{y \in E} [F(x-y), y \in B], \\ \varepsilon(F \ominus G)(x) &= \bigwedge_{y \in E} [F(x-y), y \in -B] \end{aligned}$$

The numerical geodesic dilation is obtained by replacing the binary dilation by its numerical version in the binary

geodesic formalism. For B large enough, the dilation becomes idempotent. It is called then the reconstruction opening of F inside the mask function M (Fig. 8 right).

The operations based on flat structuring elements commute under anamorphosis of the gray levels, and are the only ones to do it. This remarkable property implies three very useful consequences:

1. It makes the processing independent of the creation of the image. For example, the angiograph below may, or may not, have been obtained by a camera equipped with the so called “ γ correction” which takes the logarithm of the signal. A flat opening γ ensures us that

$$\log[\gamma(F)] = \gamma[\log(F)].$$

2. An n-bits image is transformed into an n-bits image, and in particular the indicator functions are preserved.
3. Reducing the dynamic of function F does not damage the processing. For example, in demographic data, F often range from 1 to 10^5 , but then $\sqrt{F}$ ranges from 1 to 512 and can be considered as a usual image of 9 bits.

An Example

In ophthalmology, the presence of aneurysms on retina is the sign of diabetes. How to extract them from an angiograph?

The left part of Fig. 9 depicts the angiograph F of the retina of a diabetic patient. The aneurysms consist of small white spots, but they are blurred by several vessels of various thicknesses and by the heterogeneity of the background.

Mathematical Morphology, Fig. 8 Left: Geodesic flat dilation; right: and reconstruction opening

Mathematical Morphology, Fig. 9 Left: Retina image; right: residue of a flat opening by segments

The first idea here is to perform, in all directions, openings by linear structuring elements, small but longer than the diameters of the aneurysms, and to take their union $\gamma(F)$ over all directions. In practice the directional average is performed in

the three directions of a hexagonal grid. The segments are included inside the long narrow tubes that are the vessels, which therefore belong to the opening and should disappear in the residue $F - \gamma(F)$. One can see this residue in Fig. 9

Mathematical Morphology, Fig. 10 Left: reconstruction opening of the angiograph; right: corresponding residue

(right). The former gray background is now uniformly black, which is nice, but some regions of the vessels were not caught, and are mixed with the aneurysms in the residue.

This partial result suggests to replace the adjunction opening by a (still flat) reconstruction opening which invades the vessels.

Figure 10 (left) depicts the reconstruction opening $\gamma_{\text{rec}}(F)$. All vessels have been reconstructed, and indeed the residue $F - \gamma_{\text{rec}}(F)$, visible in Fig. 10 (right), exclusively shows the aneurysms.

Summary

The above theory has suggested several developments, in various directions, that were not presented here. In geosciences, the potential of description of mathematical morphology is often used for generating synthetic images of reliefs, or of rivers networks (Sagar 2014). In physics, mathematical morphology leads to stochastic models for sets and functions, which serve in the relationships between textures and physical properties of solid materials (Jeulin 2000). In mathematics, two other branches are the concern of differential geometry (Maragos 1996) and of the digital version of the method (Kiselman 2020; Najman et al. 2005).

Matheron, Georges

Jean Serra
Centre de Morphologie Mathématique, Ecole des Mines,
Paristech, Paris, France

Biography

G. Matheron, who was born in Paris in December 1930, entered the prestigious Ecole Polytechnique in 1949 and the Ecole des Mines de Paris two years later. In 1952, he landed in Algeria with wife and child for working at the Algerian Mining Survey. He took over its scientific management in 1956, then its general management (1958). Starting from the works of Krige, from South Africa, and de Wijs, from the Netherlands, he created a theory for estimating mining resources he named Geostatistics. He designed the basic mathematical notion of a variogram, which is both the key for estimation problems and excellent tool for the describing spatial variability within mineral deposits.

He invented random functions with stationary increments, while being skeptical about the underlying

probabilistic framework. Every deposit is a unique phenomenon. Studied in itself, it does not enter the scope of probabilities. It was within that semi-random framework that G. Matheron wrote his two volumes “*Trait de Gostatistique Applique*” in 1962, which was based upon the Algerian experience. He defended his PhD thesis in 1963, in which the deterministic and random parts of his approach were developed successively. But G. Matheron waited 20 years before formulating, in *Estimating and Choosing* (Matheron 1989), which choice to make of either approach according to the context.

In 1968, the Ecole des Mines de Paris gave G. Matheron the opportunity to create the Centre de Morphologie Mathématique, in Fontainebleau. From that time onward, geostatistics gained international recognition, and requests for mining estimations arrived from the five continents. In 1971 he wrote the notes for a course on the theory of regionalized variables (Matheron 1971) which subsequently became the “bible” for ore reserve estimation in mining industry, although it was not published as a book until 2019 (Pawlowsky-Glahn and Serra 2019)! He was also asked to evaluate oil reservoirs, to map atmospheric pressures, submarine hydrography, etc. G. Matheron responded to these requests by inventing, in 1969, the theory of universal kriging which does not require the stationarity constraint, and also inventing nonlinear geostatistics in 1973 for predicting statistical distributions of ore grades in mining panels (Fig. 1).

The mining problem of the suitability of grade for grinding led him and Jean Serra to extend the concept of variogram to that of the hit-or-miss transformation, then to that of set opening. They called this new branch of science mathematical morphology, which became progressively independent of geostatistics. G. Matheron extracted from this newly developed morphological applications some general approaches, which could be conceptualized, such as granulometry, increasing operators, Poisson hyper-planes, and Boolean sets, and gathered them into the book entitled “*Random Sets and Integral Geometry*,” in 1975 (Matheron 1975).

In the 1980s, G. Matheron based Mathematical Morphology on the broader level of the complete lattices, thus providing a common approach to sets, functions, and partitions, and constructed the theory of the increasing and idempotent operators that he called morphological filtering (Matheron 1988). He retired in 1995 and passed away five years later.

Definition

Matrices are one of the most powerful tools in mathematics and geosciences with applications in Earth system science. The evolution of the concept of matrices is the result of an attempt to obtain compact and simple methods of solving system of linear equations. A matrix is an ordered rectangular array of numbers or functions. The numbers or functions are called the elements or the entries of the matrix. We denote matrices by capital letters. The following are some examples of matrices:

$$A = \begin{bmatrix} 2 & 12 \\ 4 & 5 \\ 3 & 1 \end{bmatrix}, B = \begin{bmatrix} 1 & 2 \\ 14 & 15 \end{bmatrix}, C = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 10 \end{bmatrix}$$

In the above examples, the horizontal lines of elements are said to constitute rows of the matrix and the vertical lines of elements are said to constitute columns of the matrix. Thus A has 3 rows and 2 columns, B has 2 rows and 2 columns while C has 2 rows and 3 columns.

Matrix algebra as a subset of linear algebra focuses primarily on the basic concepts and solution techniques. Numerous problems that are addressed in engineering sciences and mathematics are solved by properly setting up a system of linear equations.

Introduction

Order of a Matrix

A matrix containing n rows and m columns is called a matrix having an order of $n \times m$ (read as n by m). The total number of elements in a $n \times m$ matrix is nm . In general, a matrix containing n rows and m columns is represented as

$$A_{n,m} = \begin{bmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,m} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} & a_{n,2} & \cdots & a_{n,m} \end{bmatrix}_{n \times m}$$

Types of Matrices

Below are the different types of matrices:

Column Matrix: When a matrix has only one column, it is said to be a column matrix. For example:

$$A_{n,1} = \begin{bmatrix} a_{1,1} \\ a_{2,1} \\ \vdots \\ a_{n,1} \end{bmatrix}_{n \times 1}$$

Row Matrix: When a matrix has only one row, it is said to be a row matrix. For example:

$$A_{1,m} = [a_{1,1} \ a_{1,2} \ \dots \ a_{1,m}]_{1 \times m}$$

Square Matrix: A matrix having number of rows equal to the number of columns, is said to be a square matrix ($n = m$). The order of such a matrix is n . For example matrix A (shown below) is a square matrix of order $n \times n$:

$$A_{n,n} = \begin{bmatrix} a_{1,1} & a_{1,2} & \dots & a_{1,n} \\ a_{2,1} & a_{2,2} & \dots & a_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} & a_{n,2} & \dots & a_{n,n} \end{bmatrix}_{n \times n}$$

Diagonal Matrix: A diagonal matrix is a square matrix having all its non-diagonal elements as zero. For example:

$$A_{n,n} = \begin{bmatrix} a_{1,1} & 0 & \dots & 0 \\ 0 & a_{2,2} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & a_{n,n} \end{bmatrix}_{n \times n}$$

Scalar Matrix: A diagonal matrix is said to be a scalar matrix when all its diagonal elements are equal. For example:

$$A_{n,n} = \begin{bmatrix} a & 0 & \dots & 0 \\ 0 & a & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & a \end{bmatrix}_{n \times n}$$

Identity Matrix: An identity matrix is a square and diagonal matrix having all its diagonal elements as one. It is generally denoted by I_n . Scalar matrix is an identity matrix when $a = 1$. For example:

$$I_n = \begin{bmatrix} 1 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix}_{n \times n}$$

Power of a Matrix: For a matrix A of order $n \times n$, we write A^k for the product of k (scalar) copies of A times the identity as given below:

$$A^k = A \dots A I \quad (1)$$

This includes the case when $k = 0$ and $A^0 = I$.

Rank of a Matrix: The rank of a matrix A , denoted by $\text{rank} A$, is the dimension of column space of A .

Null/Zero Matrix: A null or zero matrix is a matrix having all its elements as zero. It is generally denoted by O . Scalar matrix is a null matrix when $a = 0$. For example:

$$O = \begin{bmatrix} 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 0 \end{bmatrix}_{n \times n}$$

Matrix Addition and Subtraction

Consider two matrices A and B of the same order $n \times m$ denoted as:

$$A = \begin{bmatrix} a_{1,1} & a_{1,2} & \dots & a_{1,m} \\ a_{2,1} & a_{2,2} & \dots & a_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} & a_{n,2} & \dots & a_{n,m} \end{bmatrix}_{n \times m}$$

and

$$B = \begin{bmatrix} b_{1,1} & b_{1,2} & \dots & b_{1,m} \\ b_{2,1} & b_{2,2} & \dots & b_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ b_{n,1} & b_{n,2} & \dots & b_{n,m} \end{bmatrix}_{n \times m}$$

The sum of $A + B$ is obtained by adding the corresponding elements of the given matrices. Moreover, the two matrices have to be of the same order and the resultant matrix C will also be of the same order $n \times m$ as shown below:

$$C = A + B$$

$$C = \begin{bmatrix} a_{1,1} + b_{1,1} & a_{1,2} + b_{1,2} & \cdots & a_{1,m} + b_{1,m} \\ a_{2,1} + b_{2,1} & a_{2,2} + b_{2,2} & \cdots & a_{2,m} + b_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} + b_{n,1} & a_{n,2} + b_{n,2} & \cdots & a_{n,m} + b_{n,m} \end{bmatrix}_{n \times m}$$

The difference of $A - B$ is obtained by subtracting the corresponding elements of the given matrices, the two matrices have to be of the same order and the resultant matrix C will also be of the same order $n \times m$ as shown below:

$$C = A - B$$

$$C = \begin{bmatrix} a_{1,1} - b_{1,1} & a_{1,2} - b_{1,2} & \cdots & a_{1,m} - b_{1,m} \\ a_{2,1} - b_{2,1} & a_{2,2} - b_{2,2} & \cdots & a_{2,m} - b_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} - b_{n,1} & a_{n,2} - b_{n,2} & \cdots & a_{n,m} - b_{n,m} \end{bmatrix}_{n \times m}$$

The addition of matrices satisfy the following properties:

- (i) **Commutative Law:** If two matrices A and B are of same order, then $A + B = B + A$ in case of addition of two matrices.
- (ii) **Associative Law:** If three matrices A , B , and C are of same order, then $(A + B) + C = A + (B + C)$.
- (iii) **Additive Identity:** If two matrices A and O are of same order among which O is a null matrix, then $A + O = O + A = A$ in case of addition of two matrices.

Matrix Multiplication

The multiplication or product of two matrices A of order $n \times m$ and B of order $s \times q$ can be obtained only if the number of columns in A are equal to the number of rows in B , i.e., when $m = s$. The resultant matrix C obtained by multiplying A and B will be of the order $n \times q$. The elements in C will be obtained by element wise multiplication of the rows of A and columns of B and taking sum of all these products as shown below: Let $A = [a_{i,j}]_{n \times m}$ and $B = [b_{j,k}]_{m \times q}$ ($m = s$) where $i \in [0, n]$, $j \in [0, m]$, $k \in [0, q]$, then the i_{th} row of A is $[a_{i,1}, a_{i,2}, \dots, a_{i,m}]$ and the k^{th} column of B is

$$\begin{bmatrix} b_{1,k} \\ b_{2,k} \\ \vdots \\ b_{m,k} \end{bmatrix}, \text{ then the element } c_{i,k} \text{ in the matrix } C \text{ will be:}$$

$$c_{i,k} = a_{i,1}b_{1,k} + a_{i,2}b_{2,k} + \cdots + a_{i,m}b_{m,k}$$

$$c_{i,k} = \sum_{j=1}^n a_{i,j}b_{j,k}$$

$$C = [c_{i,k}]_{n \times q}$$

Let A be $m \times n$ and let B and C have sizes for which the indicated sums and products are defined. The matrix multiplication satisfy the following properties:

- (i) $A(BC) = (AB)C + kB$
- (ii) $A(B + C) = AB + AC$
- (iii) $(B + C)A = BA + CA$
- (iv) $k(A + B) = kA + kB$
- (v) $k(AB) = (kA)B = A(kB)$, for any scalar k .

The proof of the properties are beyond the scope of this chapter.

Warnings:

1. In general, $AB \neq BA$
2. If $AB = AC$, then it is not true in general that $B = C$.
3. If a product AB is a null matrix, one cannot conclude in general that either $A = 0$ or $B = 0$.

Matrix Scalar Multiplication

Multiplication of a matrix by a scalar k is obtained by multiplying each element of the matrix with k as shown below:

$$A = \begin{bmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,m} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} & a_{n,2} & \cdots & a_{n,m} \end{bmatrix}_{n \times m}$$

then

$$kA = \begin{bmatrix} ka_{1,1} & ka_{1,2} & \cdots & ka_{1,m} \\ ka_{2,1} & ka_{2,2} & \cdots & ka_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ ka_{n,1} & ka_{n,2} & \cdots & ka_{n,m} \end{bmatrix}_{n \times m}$$

The scalar multiplication of a matrix satisfy the following properties:

- (i) $k(A + B) = kA + kB$
- (ii) $kA = Ak$
- (iii) $OA = 0$, where O is a null matrix.
- (iv) $(k + l)A = kA + lA$, where k and l are scalars.
- (v) $k(A + B) = kA + kB$
- (vi) $k(sA) = (ks)A$

Operations on Matrices

This section discusses some of the operations that can be performed on a matrix to obtain another matrix as explained below:

i. **Transpose of a Matrix:** For a matrix A of order $n \times m$, transpose of A is obtained by interchanging rows of A with columns of A . It is denoted by A^T and will have the order as $m \times n$. For example: if

$$A = \begin{bmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,m} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1} & a_{n,2} & \cdots & a_{n,m} \end{bmatrix}_{n \times m}$$

then

$$A^T = \begin{bmatrix} a_{1,1} & a_{2,1} & \cdots & a_{n,1} \\ a_{1,2} & a_{2,2} & \cdots & a_{n,2} \\ \vdots & \vdots & \ddots & \vdots \\ a_{1,m} & a_{2,m} & \cdots & a_{n,m} \end{bmatrix}_{m \times n}$$

The transpose of a matrix satisfy the following properties:

- (i) $(A + B)^T = A^T + B^T$ and $(A - B)^T = A^T - B^T$
- (ii) $(kA)^T = kA^T$, where k is a scalar.
- (iii) $(AB)^T = B^T A^T$, where A and B are matrices.
- (iv) $(A^{-1})^T = (A^T)^{-1}$
- (v) $(A^T)^T = A$

Note: The transpose of a product of matrices equals the product of their transposes in the reverse order.

ii. **Trace of a Matrix:** For a square matrix A of order $n \times n$, trace of A is the sum obtained by adding its diagonal elements. It is denoted by $tr(A)$. Trace of a matrix exist only for square matrices.

$$tr(A) = a_{1,1} + a_{2,2} + \cdots + a_{n,n}$$

The trace of a matrix satisfy the following properties:

- (i) $tr(A + B) = tr(A) + tr(B)$ and $tr(A - B) = tr(A) - tr(B)$
- (ii) $tr(kA) = ktr(A)$, where k is a scalar.
- (iii) $tr(AB) = tr(BA)$
- (iv) $tr(A^T) = tr(A)$

iii. Determinant of a Matrix:

We have studied about matrices and arithmetic of matrices in the previous sections. In this section we learn that a system of algebraic equations can be expressed in the form of matrices as shown below:

$$\begin{aligned} ax + by &= c_1 \\ cx + dy &= c_2 \end{aligned}$$

can be expressed as:

$$\begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \end{bmatrix}$$

To know whether the system of linear equations has a unique solution or not, we compute a number which defines the uniqueness of a solution and is known as the determinant (det) formulated as $det(A)$ for a matrix A as:

$$A = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

$$det(D) = ad - bc$$

The determinant of a matrix satisfy the following properties:

- (i) $det(A)$ remains unchanged even if its rows and columns are interchanged, i.e., $det(A) = det(A^T)$.
- (ii) The sign of $det(A)$ changes if any two rows or columns are interchanged. Interchanging two rows or two columns are denoted by $R_i \leftrightarrow R_j$ and $C_i \leftrightarrow C_j$ respectively. Hence, $det(A) = -det(A)$ if $R_i \leftrightarrow R_j$ or $C_i \leftrightarrow C_j$.
- (iii) The value of $det(A)$ is zero if any of the two rows or columns are identical.
- (iv) For a matrix A , if any row or column gets multiplied by a scalar value k then $det(A) = kdet(A)$.
- (v) If a matrix A can be expressed as a sum of two matrices (say B and C) then $det(A) = det(B) + det(C)$.

iv. Inverse of a Matrix

For a square matrix A of order n , A is said to be invertible if there exist another square matrix B of the same order n , such that below equation satisfies:

$$AB = BA = I$$

Then, B is called the inverse of A and is denoted by A^{-1} (read as A inverse). Moreover, if B is the inverse of A , then A is also the inverse of B . A matrix that is not invertible is sometimes called a singular matrix, and an invertible matrix is called a nonsingular matrix.

The inverse of a matrix follow the below properties:

- (i) Let $A = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$, if $ad - bc \neq 0$, then A is invertible and $A^{-1} = \frac{1}{ad-bc} \begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$. If $ad - bc = 0$, then A is not invertible. That is, a square matrix is only invertible if and only if its $det(A) \neq 0$.
- (ii) If matrix A of size $n \times n$ is invertible, then for each b in $\mathfrak{R}^n$, the equation $Ax = b$ has the unique solution $x = A^{-1}b$.

- (iii) If A is an invertible matrix, then A^{-1} is also invertible and $(A^{-1})^{-1} = A$.
- (iv) If A and B are $n \times n$ invertible matrices, then so is AB , then the inverse of AB is the product of A and B in the reverse order as: $(AB)^{-1} = B^{-1}A^{-1}$.
- (v) If A is an invertible matrix, then so is A^T , then the inverse of A^T is the transpose of A^{-1} as: $(A^T)^{-1} = (A^{-1})^T$.

Note: The product of $n \times n$ invertible matrices is invertible, and the inverse is the product of their inverses in the reverse order.

Eigenvalues and Eigenvectors

In the previous section we discussed about scalar and matrix multiplication with matrix A . In this section, we will discuss the results and outcome of multiplying a vector $\vec{p}$ with the matrix A . To define formally, let A be a matrix of order $n \times n$, $\vec{p}$ be a non-zero column vector of order $n \times 1$ and λ be a scalar. Then $\vec{p}$ is an eigenvector of A and λ is an eigenvalue of A if the below condition is satisfied:

$$A\vec{p} = \lambda\vec{p}$$

Matrix A should be square and $\vec{p}$ should be non-zero. In order to find the eigenvectors or eigenvalues given A , we need to find a non-zero vector $\vec{p}$ and a scalar λ such that $A\vec{p} = \lambda\vec{p}$, which can be further solved as follows:

$$\begin{aligned} A\vec{p} &= \lambda\vec{p} \\ A\vec{p} - \lambda\vec{p} &= \vec{0} \\ (A - \lambda I)\vec{p} &= \vec{0} \end{aligned}$$

The eigenvalues and eigenvectors of a matrix satisfy the following properties for an invertible matrix A of order n :

- (i) For a triangular matrix A , the diagonal values of A are the eigenvalues of A .
- (ii) If λ is an eigenvalue of A with eigenvector $\vec{p}$, then $\frac{1}{\lambda}$ is an eigenvalue of A^{-1} with eigenvector $\vec{p}$.
- (iii) Eigenvalue of A and A^T is same as λ .
- (iv) Sum of eigenvalues of A is equal to the trace of A .
- (v) The product of eigenvalue of A is equal to the determinant of A .

Case Study

In this section, examples on matrix operations and arithmetic are discussed.

Problem 1: If a matrix has 9 elements then what are the possible order of the matrix?

Matrix Algebra, Table 1 Number of chairs and tables made in different factories

Factory	Number of chairs	Number of tables
I	23	12
II	34	15
III	30	18

Solution 1: The order of the matrix is given by the product of the number of rows n and number of columns m . Therefore, we need to find the real values of m and n such that $mn = 9$. Thus, the possible order of the matrix can be: 1×9 , 9×1 , 3×3 .

Problem 2: Consider Table 1 representing the number of tables and chair made in factories I, II and III. Represent this information in terms of a 3×2 matrix. What does the element in the second row and third column represent?

Solution 2: From the Table, the number of rows are three and number of columns are two. Hence, the order of the matrix is 3×2 and the matrix can be written as shown below:

$$A = \begin{bmatrix} 23 & 12 \\ 34 & 15 \\ 30 & 18 \end{bmatrix}_{3 \times 2}$$

The element in the second row and third column represent that 15 tables are made in the factory II.

Problem 3: Let A , B , and C be the three matrices given below:

$$A = \begin{bmatrix} 2 & 12 \\ 4 & 5 \\ 3 & 1 \end{bmatrix}_{3 \times 2} \quad B = \begin{bmatrix} 1 & 2 \\ 14 & 15 \\ 31 & 1 \end{bmatrix}_{3 \times 2} \quad C = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 10 \end{bmatrix}_{2 \times 3}$$

Find: (i) $A + B$ (ii) $A - 2B$ (iii) $3(A + B)$ (iv) AC

Solution 3: (i) Let $D = A + B$

$$\begin{aligned} D &= \begin{bmatrix} 2 & 12 \\ 4 & 5 \\ 3 & 1 \end{bmatrix} + \begin{bmatrix} 1 & 2 \\ 14 & 15 \\ 31 & 1 \end{bmatrix} \\ D &= \begin{bmatrix} 2+1 & 12+2 \\ 4+14 & 5+15 \\ 3+31 & 1+1 \end{bmatrix} = \begin{bmatrix} 3 & 14 \\ 18 & 20 \\ 34 & 2 \end{bmatrix} \end{aligned}$$

(ii) Let $E = A - 2B$

$$E = \begin{bmatrix} 2 & 12 \\ 4 & 5 \\ 3 & 1 \end{bmatrix} - 2 \begin{bmatrix} 1 & 2 \\ 14 & 15 \\ 31 & 1 \end{bmatrix}, E = \begin{bmatrix} 2-2 & 12-4 \\ 4-28 & 5-30 \\ 3-62 & 1-2 \end{bmatrix}$$

$$E = \begin{bmatrix} 0 & 8 \\ -24 & -25 \\ -59 & -1 \end{bmatrix}$$

(iii) From (i) $D = A + B$ hence, let $F = 3D$

$$F = 3 \begin{bmatrix} 3 & 14 \\ 18 & 20 \\ 34 & 2 \end{bmatrix}, F = \begin{bmatrix} 3 \times 3 & 14 \times 3 \\ 18 \times 3 & 20 \times 3 \\ 34 \times 3 & 2 \times 3 \end{bmatrix}$$

$$F = \begin{bmatrix} 9 & 42 \\ 54 & 60 \\ 102 & 6 \end{bmatrix}$$

(iv) Let $G = AC$

$$G = \begin{bmatrix} 2 & 12 \\ 4 & 5 \\ 3 & 1 \end{bmatrix}_{3 \times 2} \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 10 \end{bmatrix}_{2 \times 3}$$

$$G = \begin{bmatrix} 2 \times 1 + 12 \times 4 & 2 \times 2 + 12 \times 5 & 2 \times 3 + 12 \times 10 \\ 4 \times 1 + 5 \times 4 & 4 \times 2 + 5 \times 5 & 4 \times 3 + 5 \times 10 \\ 3 \times 1 + 1 \times 4 & 3 \times 2 + 1 \times 5 & 3 \times 3 + 1 \times 10 \end{bmatrix}_{3 \times 3}$$

$$G = \begin{bmatrix} 50 & 64 & 126 \\ 24 & 33 & 62 \\ 7 & 11 & 19 \end{bmatrix}_{3 \times 3}$$

Problem 4: Let A be a matrix as given below:

$$A = \begin{bmatrix} 2 & 12 & 1 \\ 4 & 5 & 1 \\ 3 & 1 & 1 \end{bmatrix}_{3 \times 3}$$

Find: (i) A^T (ii) $\text{tr}(A)$ (iii) $\det(A)$ (iv) A^{-1}

Solution 4:

(i) A^T can be obtained by interchanging rows and columns as shown below:

$$A^T = \begin{bmatrix} 2 & 4 & 3 \\ 12 & 5 & 1 \\ 1 & 1 & 1 \end{bmatrix}_{3 \times 3}$$

(ii) The trace of a matrix can be obtained by adding the diagonal elements as shown below:

$$\text{tr}(A) = 2 + 5 + 1$$

$$\text{tr}(A) = 8$$

(iii) Determinant of matrix A is:

$$\det(A) = 2 \begin{vmatrix} 5 & 1 \\ 1 & 1 \end{vmatrix} - 12 \begin{vmatrix} 4 & 1 \\ 3 & 1 \end{vmatrix} + 1 \begin{vmatrix} 4 & 5 \\ 3 & 1 \end{vmatrix}$$

$$\det(A) = 2((5 \times 1) - (1 \times 1)) - 12((4 \times 1) - (1 \times 3))$$

$$+ 1((4 \times 1) - (5 \times 3)) \det(A) = -15$$

Problem 5: Find rank of the matrix $A = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 1 & 4 \\ 3 & 0 & 5 \end{bmatrix}$

Solution 5: Reduce A into its echelon form:

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 0 & -3 & -2 \\ 0 & 0 & 0 \end{bmatrix}$$

The above matrix is in row echelon form. Number of non-zero rows = 2. Hence the rank of matrix $A = 2$.

Problem 6: Find eigenvalues of the matrix $A = \begin{bmatrix} -3 & 15 \\ 3 & 9 \end{bmatrix}$ and find eigenvector for each eigenvalue.

Solution 6:

$$\det(A - \lambda I) = \begin{vmatrix} -3 & 15 \\ 3 & 9 \end{vmatrix} - \lambda \begin{vmatrix} 1 & 0 \\ 0 & 1 \end{vmatrix}$$

$$\det(A - \lambda I) = \begin{vmatrix} -3 - \lambda & 15 \\ 3 & 9 - \lambda \end{vmatrix}$$

$$\det(A - \lambda I) = ((-3 - \lambda) \times 9) - (15 \times 3)$$

$$= (-3 - \lambda)(9) - 45$$

$$= -27 - 9\lambda - 45$$

$$= -72 - 9\lambda$$

$$\det(A) = -15$$

Conclusion

Algebraic operations with matrices help in analyzing and solving equations in geocomputing. In this chapter we saw some basic operations for handling two or more matrices. Furthermore, the definitions and properties in this chapter also provide basic tools for handling many applications of linear algebra involving two or more matrices.

Definition

The principle of maximum entropy states that the most suitable probability model for a given system maximizes the Shannon entropy subject to the constraints imposed by the data and – if available – other prior knowledge of the system. The maximum entropy distribution is the most general probability distribution function conditionally on the constraints. In the geosciences, the principle of maximum entropy is

mainly used in two ways: (1) in the maximum entropy method (MEM) for the parametric estimation of the power spectrum and (2) for constructing joint probability models suitable for spatial and spatiotemporal datasets.

Overview

The concept of *entropy* was introduced in thermodynamics by the German physicist Rudolf Clausius in the nineteenth century. Clausius used entropy to measure the thermal energy of a machine per unit temperature which cannot be used to generate useful work. The Austrian physicist Ludwig Boltzmann used entropy in statistical mechanics to quantify the *randomness (disorder)* of a system. The statistical mechanics definition of entropy reflects the number of microscopic configurations which are accessible by the system. In the twentieth century, the concept of entropy was used by the American mathematician Claude Shannon (1948) to measure the average information contained in signals. Shannon's influential paper founded the field of *information theory*. Consequently, the terms *Shannon entropy* and *information entropy* are used to distinguish between the entropy content of signals and the mechanistic notion of entropy used in thermodynamics and statistical mechanics.

The connection between information theory and statistical mechanics was investigated in two seminal papers by the American physicist Edwin T. Jaynes (1957a, b). He showed that the formulation of statistical mechanics can be derived from the principle of maximum entropy without the need for additional assumptions. The *principle of maximum entropy* is instrumental in establishing this connection; it dictates that given partial knowledge of the system, the least biased estimate for the probability distribution maximizes Shannon entropy under the specified constraints. According to Jaynes, “Entropy maximization is not an application of a law of physics, but merely a method of reasoning that ensures that no arbitrary assumptions are made.” The work of Jaynes opened the door for the application of MEM to various fields of science and engineering that involved ill-posed problems characterized by incomplete information. Notable application areas include spectral analysis (Burg 1972), image restoration (Skilling and Bryan 1984), geostatistics (Christakos 1990), quantum mechanics, condensed matter physics, tomography, crystallography, chemical spectroscopy, and astronomy, among others (Skilling 2013).

Methodology

According to *Laplace's principle of indifference*, if prior knowledge regarding possible outcomes of an experiment is unavailable, the uniform probability distribution is the most impartial choice. MEM employs this principle by

incorporating data-imposed constraints in the model inference process. The MEM probability model depends on the constraints used: The MEM model for a nonnegative random variable with known mean is the exponential distribution. If the constraints include the mean and the variance, the Gaussian (normal) distribution is obtained. In the case of multivariate and spatially distributed processes, the MEM model constrained on the mean and the covariance function is the joint Gaussian distribution.

Notation

In the following, it is assumed that $X = (X_1, \dots, X_n)^T$ (T denotes the transpose) is an n -dimensional random vector defined in a probability space $(\Omega, \mathcal{F}, \mathcal{P})$, where Ω is the sample space, $\mathcal{F}$ is the sigma-algebra of events, and $\mathcal{P}$ is the probability measure. The realizations $\mathbf{x} \in \mathbb{R}^n$ of the random vector $\mathbf{X}$ can take either discrete or continuous values.

The expectation of the function $g(\mathbf{X})$ over the ensemble of states $\mathbf{x}$ is denoted by $\mathbb{E}[g(\mathbf{X})]$. The expectation involves the *joint probability mass function* (PMF) $p(\mathbf{x})$ if the random variables X_i take discrete values or the *joint probability density function* (PDF) $f(\mathbf{x})$ if the X_i are continuous. We use the *trace operator*, Tr , as a unifying symbol to denote summation (if the random variables X_i are discrete) or integration (if the X_i are continuous) over all probable states $\mathbf{x}$.

General Formulation

Assuming that the PMF $p(\mathbf{x})$ (in the discrete case) or the PDF $f(\mathbf{x})$ (in the continuous case) is known, Shannon's entropy can be expressed as

$$S = - \sum_{\mathbf{x} \in \Omega} p(\mathbf{x}) \ln p(\mathbf{x}), \quad \text{discrete}, \quad (1)$$

$$S = - \int_{\mathbb{R}} dx_1 \dots \int_{\mathbb{R}} dx_n f(\mathbf{x}) \ln f(\mathbf{x}), \quad \text{continuous}. \quad (2)$$

The entropy for both the discrete and continuous cases can be expressed as $S = -\mathbb{E}[\ln f(\mathbf{x})]$, where $f(\cdot)$ here stands for the PMF in the discrete case and the PDF in the continuous case. For the sake of brevity, in the following, we use $f(\cdot)$ to denote the PDF or the PMF and refer to it as “probability distribution.” We also use the term “summation” to denote either summation (for discrete variables) or integration (for continuous variables) over all possible states $\mathbf{x}$.

Let $\{g_m(\mathbf{x})\}_{m=1}^M$ represent a set of M sampling functions, the averages of which can be determined from the data

(observations). We will denote sample averages by means of $\overline{g_m(\mathbf{x})}$. Such sampling averages can include the mean, variance, covariance, higher-order moments, or more complicated functions of the sample values. Then, according to the *principle of maximum entropy*, the probability distribution should respect the constraints (the symbol $\equiv$ denotes equivalence)

$$\mathbb{E}[g_m(\mathbf{x})] \equiv \text{Tr}_{\mathbf{x}}[g_m(\mathbf{x})f(\mathbf{x})] = \overline{g_m(\mathbf{x})}, \quad m = 1, \dots, M, \quad (3)$$

where $\text{Tr}_{\mathbf{x}}[\cdot]$ denotes the “summation” over all possible states $\mathbf{x}$. The above equations are supplemented by the *normalization constraint* $\text{Tr}_{\mathbf{x}}f(\mathbf{x}) = 1$ which ensures the proper normalization of the probability distribution.

The maximum entropy (henceforward, *MaxEnt*) distribution maximizes the entropy under the above constraints. This implies a constrained optimization problem defined by means of the following Lagrange functional

$$\begin{aligned} \mathcal{L}[f] = & -S + \sum_{m=1}^M \lambda_m [\overline{g_m(\mathbf{x})} - \text{Tr}_{\mathbf{x}}g_m(\mathbf{x})f(\mathbf{x})] \\ & + \lambda_0 [1 - \text{Tr}_{\mathbf{x}}f(\mathbf{x})]. \end{aligned} \quad (4)$$

The minimization of $\mathcal{L}[f]$ can be performed using the calculus of variations to find the stationary point of the Lagrange functional. At the stationary point, the functional derivative $\delta\mathcal{L}/\delta f$ vanishes, i.e.,

$$0 = \frac{\delta\mathcal{L}}{\delta f} = \ln f(\mathbf{x}) + 1 - \sum_{m=1}^M \lambda_m g_m(\mathbf{x}) - \lambda_0.$$

The above equation leads to the *MaxEnt probability distribution*

$$f(\mathbf{x}) = \frac{1}{Z} \exp \left[\sum_{m=1}^M \lambda_m g_m(\mathbf{x}) \right], \quad \ln Z = 1 - \lambda_0, \quad (5)$$

where the constant Z is the so-called partition function which normalizes the MaxEnt distribution. Since $f(\mathbf{x})$ is normalized by construction, it follows from Eq. (5) that

$$Z = \text{Tr}_{\mathbf{x}} \exp \left[\sum_{m=1}^M \lambda_m g_m(\mathbf{x}) \right]. \quad (6)$$

The implication of Eqs. (5) and (6) is that λ_0 depends on the Lagrange multipliers $\{\lambda_m\}_{m=1}^M$. These need to be determined by solving the following system of M nonlinear constraint equations

$$\overline{g_m(\mathbf{x})} = \text{Tr}_{\mathbf{x}} g_m(\mathbf{x}) f(\mathbf{x}) = \frac{\partial Z}{\partial \lambda_m}, \quad m = 1, \dots, M. \quad (7)$$

In spatial and spatiotemporal problems, the constraints involve joint moments of the field (Christakos 1990, 2000; Hristopulos 2020). The constraints are expressed in terms of real-space coordinates. In the case of time series analysis, it is customary to express the MEM solution in the spectral domain (see next section).

Spectral Analysis

MEM has found considerable success in geophysics as a method for estimating the power spectrum of stationary random processes (Burg 1972; Ulrych and Bishop 1975). In spectral analysis, MEM is also known as *all poles* and *autoregressive (AR) method*.

For a time series with a constant time step δt , the MEM power spectral density at frequency f is given by

$$P(f) = \frac{c_0}{|1 + \sum_{m=1}^M c_m \exp(2\pi i f m \delta t)|^2}, \quad -f_N \leq f \leq f_N, \quad (8)$$

where $f_N = 1/2\delta t$ is the Nyquist frequency (i.e., the maximum frequency which can be resolved with the time step δt) and $\{c_m\}_{m=0}^M$ are coefficients which need to be estimated from the data.

The term “all-poles” method becomes obvious based on Eq. (8), since $P(f)$ has poles in the complex plane. The poles coincide with the zeros in the denominator of the fraction that appears in the right-hand side of Eq. (8). The connection with AR time series models of order m lies in the fact that the latter share the spectral density given by Eq. (8). The order of the AR model which is constructed based on MaxEnt is equal to the maximum lag, $m\delta t$, for which the auto-covariance function can be reliably estimated based on the available data.

Applications

Maximum entropy has been extensively used in many disciplines of geoscience. Notable fields of application include geophysics, seismology and hydrology, estimation of rainfall variability and evapotranspiration, assessment of landslide susceptibility, classification of remote sensing imagery, prediction of categorical variables, investigations of mineral potential prospectivity, and applications in land use and climate models.

The principle of maximum entropy is used in Bayesian inference to obtain prior distributions (Skilling 2013). This

connection has been exploited in the Bayesian MaxEnt (BME) framework for spatial and spatiotemporal model construction and estimation (Christakos 1990, 2000). BME allows incorporating prior physical knowledge of the spatial or spatiotemporal process in the probability model. In spatial estimation problems, the application of the method of maximum entropy assumes that the mean, covariance, and possibly higher-order moments provide the spatial constraints for random field models. A different approach proposes local constraints that involve geometric properties, such as the square of the gradient and the linearized curvature of the random field (Hristopulos 2020). This approach leads to spatial models with sparse precision matrix structure which is computationally beneficial for the estimation and prediction of large datasets. In recent years, various generalized entropy functions have been proposed (e.g., Rényi, Tsallis, Kaniadakis entropies) for applications that involve long-memory, non-ergodic, and non-Gaussian processes. In principle, it is possible to build generalized MEM distributions using extended notions of entropy (Hristopulos 2020). The mathematical tractability and the application of such generalized maximum entropy principles in geoscience are open research topics.

Summary or Conclusions

The notion of entropy is central in statistical mechanics and information theory. Entropy provides a measure of the information incorporated in a specific signal or dataset. The principle of maximum entropy can be used to derive probability distributions which possess the largest possible uncertainty given the constraints imposed by the data. Equivalently, maximum entropy minimizes the amount of prior information which is integrated into the probability distribution. Thus, the maximum entropy probability distributions are unbiased with respect to what is not known. The most prominent applications of maximum entropy in geoscience include the estimation of spectral density for stationary random processes and the construction of joint probability models for spatial and spatiotemporal datasets.

Synonyms

Autoregressive spectral estimation, all-poles spectral estimation

Definition

Maximum entropy spectral analysis (MESA) is the statistical estimation of the power spectrum of a stationary time series using the maximum entropy (ME) method. The resulting ME spectral estimator is parametric and equivalent to an autoregressive (AR) spectral estimator.

General Comments

In geosciences, there is a plethora of time series of interest in applied geosciences. A sequence of varve thicknesses, a seismogram or the isotopic content in a stalagmite are but three common examples in cyclostratigraphy, geophysics and paleoclimatology, respectively. The time series is modeled as a stochastic process (or random function) where a topic

of frequent interest is the estimation of its power spectrum (or spectral density) which is a function that describes the distribution of the variance (power or energy) of the time series across frequencies. In general, the power spectrum of a time series is unknown in advance and must be estimated from the experimental data. The main task of spectral analysis is thus the estimation of the power spectrum for the available data. There are many methods for the estimation of the power spectrum, like the periodogram, the Blackman–Tukey approach, multitaper estimators, singular value decomposition analysis, etc. MESA is another important spectral analysis method that must be added to the list, being a popular choice in geosciences (Ables 1974), and particularly appealing because of its high resolution and its good performance with short time series. The method was first proposed by Burg (1967).

MESA Method

The maximum entropy spectral estimator (Burg 1967; Papoulis 1984) is the spectral density $\hat{S}(\omega)$ that maximizes the entropy (E):

$$E = \int_{-\pi}^{\pi} \ln\{S(\omega)\} d\omega, \quad (1)$$

over the class of all densities $S(\omega)$ that satisfy the constraints given by making (theoretical) covariances equal to sample covariances (i.e. covariances estimated from the data):

$$\int_{-\pi}^{\pi} e^{i\omega h} S(\omega) d\omega = \hat{C}(h), \quad (2)$$

for $h \in [-q, q + 1, \dots, -1, 0, 1, \dots, q]$.

Where $\hat{C}(h) = \hat{C}(-h)$ is the estimated covariance for lag h , i is the imaginary unit and $\omega = 2\pi f$ is the angular frequency (radians per sampling interval) while f is the frequency in cycles per sampling interval.

Next, it may be shown that the ME spectral estimator has the form (Brockwell and Davis 1991):

$$\hat{S}(\omega) = \frac{\sigma_q^2}{\left| 1 + \sum_{k=1}^q a_k e^{-ik\omega} \right|^2}, \quad (3)$$

which is equal to the AR spectral estimator of order q . Strictly speaking the AR estimator provided in Eq. (3) is the ME estimator when the random function (stochastic process) is Gaussian (Papoulis 1984).

In the previous equations: σ_q^2 is the variance of a zero-mean white noise stochastic process that depends on the order q of

the AR process, and $\{a_k; k = 1, \dots, q\}$ are the q autoregressive coefficients that are also dependent on the chosen order q . These $q + 1$ parameters must be estimated from the experimental data in order to apply the ME spectral estimator of Eq. (3).

A possibility for obtaining the estimation of the previous $q + 1$ parameters is to use the Yule-Walker equations (Papoulis 1984). However, in order to avoid the inversion of large covariance matrixes, it is possible to use the Durbin-Levinson algorithm (Brockwell and Davis 1991), which gives the estimates of the AR coefficients and noise variance recursively. Another popular recursive algorithm is given by Burg (1967) which uses estimates of forward and backward estimation errors and their mean square values (Papoulis 1984).

Advantages of MESA

High frequency resolution. MESA is capable of resolving discrete frequencies close together even in short time series.

Consistent power spectrum estimates. In this sense, MESA produces neither negative estimates nor those that do not coincide with their sample covariance values.

There is no leakage of power between nearby frequencies. MESA does not experience the side lobe problem that is

common with other spectral estimators and that is caused by the use of window functions.

Efficient spectrogram analysis. MESA can be efficiently used for estimating the spectrogram (Pardo-Igúzquiza and Rodríguez-Tovar 2006) because it achieves good results with short time series.

Difficulties in the Application of MESA

An important decision is the choice of an optimum autoregressive order q for the MESA estimator given in Eq. (3). Many alternatives have been proposed. Some methods are based on criteria like the Akaike information criterion or the final error prediction (Ulrych and Bishop 1975). The order is often chosen empirically with a value between $N/5$ and $N/2$, N being the number of experimental data points. $2N/\ln(2N)$ is another popular empirical choice. If the chosen order is small, the variance of the estimates is small, but the bias is large, while if the chosen order is large, the bias is small, but the variance increases.

An optimal choice of the order q results in problems of spectrum line splitting, frequency shifting, spurious peaks and biased power estimation. However, these problems are

Maximum Entropy Spectral Analysis, Fig. 1 Simulated data time series (Data in the figure) equal to the addition of signal (Signal in the figure) and noise (Noise in the figure). The similarity of signal and noise and how the spectral content is hidden in the data and not at all evident

are both remarkable. The number of data points is 200, which can be considered a short time series. The signal has been shifted upwards by adding a value of 15 and the noise has been shifted downwards by a value of -15 to avoid the overlap and provide a clearer representation

given in A. The vertical dashed red lines give the location of the theoretical frequencies of the sinusoids of the signal

Maximum Entropy Spectral Analysis, Fig. 3 (a): MESA estimated power spectrum of the observed data with a simulation scheme identical to the one used in Fig. 1 but extending the length of the different time series from 200 to 2000 data points. (b): Achieved confidence level of

the estimated power spectrum given in A. The vertical dashed red lines show the location of the theoretical frequencies of the sinusoids of the signal

common to all spectral methods if the data are of low quality (few data points, irregular sampling, high level of noise, etc.).

Another difficulty is the statistical evaluation of the reliability or uncertainty of the estimated power spectrum. This evaluation is complex and must be based on strong assumptions regarding the model that should be followed by the experimental data (Baggeroer 1976). This problem has been solved by using the computer intensive permutation test method (Pardo-Igúzquiza and Rodríguez-Tovar 2005). The permutation test is easy to apply, non-parametric but based on the computer intensive method. The original time series is ordered at random (a permutation sequence) many times (for example 5000 times) and for each disordered sequence the ME power spectrum is estimated. The statistical significance of the power spectrum estimated from the original time series may then be assessed by calculating how many times it is higher than the power spectrum at the same frequency for all permutation sequences.

Examples of Application

The first example is a short time series (200 data points) that has been simulated following the model: observed data equal to signal plus noise. The signal consists of the superposition of six sinusoids of equal amplitude with frequencies forming three pairs: one in the low (0.05 and 0.06), another in the

middle (0.25 and 0.26) and a third pair in the high frequencies (0.42 and 0.43), where all these are given in cycles per sampling interval that is considered unity. The amplitude of each sinusoid gives a variance of the signal equal to 3. The white noise is a sequence of Gaussian numbers drawn from a Gaussian distribution with mean zero and variance 12. Thus, the signal-to-noise ratio (SNR) of variances is $3/12 = 0.25$. The observed data, signal and noise are represented in Fig. 1. The high similitude of observed data and noise is evident because of the low SNR and it can be correctly said that the signal is hidden in the noise, thus it is a very challenging case. The estimated power spectrum (with $p = 67$) of the time series of observed data is shown in Fig. 2A and the achieved confidence level of the permutation test is shown in Fig. 2B. Figure 2A demonstrates how the three couples of sinusoidal components have been identified although with a frequency shift in the lowest frequency component. Figure 2B demonstrates how all the components have been identified with high statistical significance ($> 99\%$) except the fourth component, i.e. the high frequency component in the middle frequencies. When the number of data points of those observed (signal + noise) is increased to 2000, Figs. 3A (with $p = 150$) and 3B show how these difficulties disappear.

The second example is a sequence of real data (oxygen isotope of $\delta^{18}\text{O}$) measured along a drill core sample of ocean sediment (Raymo et al. 1992). The time series has been represented in Fig. 4 and it has 866 data points with a

Maximum Entropy Spectral Analysis, Fig. 4 Time series of 866 data points of oxygen isotope $\delta^{18}\text{O}$ (Raymo et al. 1992)

Maximum Entropy Spectral Analysis, Fig. 5 (a): MESA estimated power spectrum of the time series shown in Fig. 4. (b): Achieved confidence level of the estimated power spectrum given in A

sampling interval of 3 kyrs. The power spectrum estimated by MESA with an autoregressive order $p = 150$ is shown in Fig. 5A and the significance level achieved by the permutation test is shown in Fig. 5B. Figure 5B demonstrates how the most statistically significant frequencies correspond to periodicities of 19, 22.4, 41, 77, 97, 115 and 230 kyrs. These estimated cycles are in line with Milankovitch periodicities of precession (19 and 22.4 kyrs), obliquity (41 kyrs) and short eccentricity (97 and 115 kyrs). The 77 kyrs can be explained as a combination tone of the main periodicities and the 230 kyrs a harmonic of eccentricity.

Summary

Maximum entropy spectral analysis is a high-resolution spectral estimator that has been widely used in geosciences. It is based on choosing the spectrum that corresponds to the most random (i.e. unpredictable) time series whose covariance function coincides with the known values (Burg 1975). It comes out that the solution to choosing the maximum entropy spectrum is equal to the autoregressive estimator of the power spectrum. The main problem is to select an optimal value for the autoregressive order q . There are several proposals for choosing a reasonable order of the estimator and the statistical significance of the estimated spectrum can be easily assessed by a computer intensive method like the permutation test.

Maximum Likelihood

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International Institute of Information Technology Bangalore, Electronic City, Bangalore, Karnataka, India

Definition

Estimating a probability distribution to fit the available observed data is an important process required by statisticians and data analysts. Such estimation is required for prediction/forecasting, missing data analysis, learning functions with uncertain outcomes, etc. where the estimated probability distribution model of the observed data provides the representative behavior. Once a set of random variables has been identified to model specific observation data, a joint probability distribution is to be defined on the set. The joint probability density function of n independent and identically distributed (i.i.d.) observations data $x_1, x_2, \dots, x_n$ from this process, where the probability function is conditioned on a set of parameters θ , is given by likelihood function $f(x_1, x_2, \dots, x_n) = \prod_{i=1}^n f(x_i|\theta) = L(\theta|\mathbf{x})$. This function is representative of all information of the sample population from which the observations are made, and this information is what gets used for estimation in the form of an estimator.

The widely used estimators are classified based on the distribution type, as parametric, semi-parametric, and non-parametric estimation methods (Greene 2012). Maximum

likelihood estimation (MLE) is a classical parametric estimation method, generalized method of moments (GMM) is a semi-parametric estimation method, and kernel density estimation is a non-parametric estimation method. Parametric estimators provide the advantage of a consistent approach owing to which it can be applied to a variety of estimation problems. However, it suffers from the limitation of the robustness of underlying assumptions used, when imposing normal, logistic, or any other widely used distributions to fit the given data. The semi- and nonparametric distributions alleviate the restriction of the model but then often suffer from the issue of providing a range of probabilities as outcomes.

As the name suggests, MLE maximizes the likelihood function (Fisher 1912), thus, providing the argument of the likelihood function, θ , with the most probable (likely) occurrence. This is the most intuitive method, as it stems from the joint probability density or mass function of continuous and discrete random variables, respectively. The principle of maximum likelihood states that the most optimal choice of the estimator $\hat{\theta}$ from a set of estimators θ is the one that makes the observed data $\mathbf{x}$ most probable. Thus, this principle provides a choice of an asymptotically efficient estimator for a parameter or a set of parameters.

To improve the practical implementation of determining the maximum value of $L(\theta | \mathbf{x})$, its logarithm, referred to as log-likelihood is widely used as the likelihood function in MLE. Log-likelihood function is given as $\ln L(\theta | \mathbf{x}) =$

$\ln \left(\prod_{i=1}^n f(x_i | \theta) \right) = \sum_{i=1}^n \ln f(x_i | \theta)$. The use of log-likelihood functions is more popular due to three key reasons. Firstly, it gives an accurate outcome, as the logarithm of the function attains the maximum when the function is at its maximum value. Secondly, in terms of convenience of using log-likelihood functions instead of the likelihood functions themselves, for most distributions, and especially the widely used exponential families of distributions, the former give simpler terms for extremum computation than the latter. Thirdly, using additive models is more convenient in most mathematical operations, and thus, the summation in log-likelihood functions is more convenient than the equivalent product in the likelihood function. Thus, the MLE widely considers the logarithm function as the likelihood function.

Overview

A maximum likelihood estimator is a type of extremum estimator, that optimizes a criterion function, which is either $L(\theta | \mathbf{x})$ or $(\ln L(\theta | \mathbf{x}))$ in the case of MLE, and the outcome is the estimator, which is the argument θ at its extremum value.

Least-squares and GMM are other extremum estimators. MLE and least-squares estimator fall under the subclass of M-estimators, where the criteria function is a sum of terms (Greene 2012). Thus, for maximum likelihood estimation of given independent and identically distributed (i.i.d) observation data $x_1, x_2, \dots, x_n$, and selected parameters θ , its estimated value is given as: $\hat{\theta} = \arg \max \left[\frac{1}{n} \sum_{i=1}^n \ln f(x_i | \theta) \right]$.

In practice, estimation properties are evaluated to determine the optimal model within a class of estimators. Maximum likelihood methods have desirable properties, such as the outcomes tend to have minimum variance, thus the smallest confidence interval, and they have approximately normal distributions and sample variances to be used for confidence bounds determination and hypothesis testing. Being an M estimator, MLE has desirable properties of consistency and asymptotic normality. Suppose θ_0 is the unknown parameter of the selected model for which θ is the approximated one, *consistency* of the estimator implies $\hat{\theta} \rightarrow \theta_0$, as $n \rightarrow \infty$. *Asymptotic normality* of $\hat{\theta}$ implies that in addition to the estimator definitely converging to the unknown parameter, it does so at the rate of $\frac{1}{\sqrt{n}}$. This implies faster convergence with larger observations/sample set, given as $\sqrt{n}(\hat{\theta} - \theta_0) \rightarrow^d N(0, \sigma_{\theta_0}^2)$, where $\sigma_{\theta_0}^2$ is called as the asymptotic variance of the estimate $\hat{\theta}$ (Panchenko 2006). At the same time, MLE suffers from the limitations of specificity of the likelihood equations, nontrivial numerical estimation, heavy bias in the case of small samples, and sensitivity to initial conditions (Heckert and Filliben 2003).

MLE is attributed to R. A. Fisher owing to the official documented appearance of the term “maximum likelihood” in literature (Fisher 1912). However, there is evidence of the usage of MLE prior to 1912, albeit with the use of different terminology, e.g., “most probable.” Early variants of MLE include estimating using the maximum value of the posterior distribution, referred to as inverse probability, and minimum of variance of “probable errors” (Edgeworth 1908). The seminal works by both Edgeworth and Fisher have independently established the efficiency of maximum likelihood and the minimization of the asymptotic variance of M-estimators (Pratt 1976). While Edgeworth and predecessors, including Gauss, Laplace, and Hagen, used the principle of inverse probability using posterior mode as an estimator, Fisher replaced the posterior mode with the MLE, thus achieving invariance (Hald 1999). Today, the widespread use of MLE may be equally attributed to both Edgeworth and Fisher for providing proof of the optimality of $\hat{\theta}$. Apart from the use of the maximum likelihood principle for estimation, it can also be effectively used for testing a model using the log-likelihood ratio statistic (Akaike 1973). Thus, these two implications of the principle can be combined to a single problem of statistical decision.

Applications

MLE has been used in geoscientific applications for a long time, which is evident from the fact that geodesists and civil engineers have been early adopters of the predecessors to MLE (Hald 1999). Today, MLE in itself is used in a variety of geoscientific applications, of which a few are listed here. It is one of the methods used in predicting the occurrence of mineral deposits at a regional scale, electrofacies classification in reservoirs for petroleum engineering, parameter estimation for reservoir modeling using multimodal data (geophysical logs, remote sensing images, etc.), and quantifying epistemic uncertainty in geostatistical applications pertaining to natural resources and environment (Sagar et al. 2018).

The principle of maximum likelihood is also extended to semantic classification, applied to satellite images (Bolstad and Lillesand 1991). In maximum likelihood classification, the different classes, which are present in the bands of multispectral satellite images, are modeled using different normal distributions, and the labeling is done for each pixel-based on the probability it belongs to each class.

Future Scope

The scope of applications of utilizing maximum likelihood is continuously growing larger, owing to its popularity over several decades. Increasingly, the maximum likelihood-based methods, such as MLE and classification, use combinations of methods, e.g., polynomial methods, to improve the efficiency of the data analysis methods used in the application. Overall, the maximum likelihood estimation is an efficient statistical modeling and inference method.

McCammon, Richard B.

Michael E. Hohn
Morgantown, WV, USA

Fig. 1 Richard B. McCammon, courtesy of Dr. Richard McCammon

Biography

Richard McCammon, founding member of the International Association for Mathematical Geology (IAMG), Krumbein Medalist, editor, longtime scientist with the US Geological Survey (USGS), and researcher in geologic resources, was born on December 3, 1932, in Indianapolis, Indiana (USA), son of Bert McCammon, a pharmacist in that city, and wife Mary. He graduated from Broad Ripple High School in 1951 and went on to college at the Massachusetts Institute of Technology, receiving a Bachelor's degree in 1955. His initial ambition was to receive a degree in chemical engineering, but in his junior year he changed his major to geology, realizing the appeal of working outdoors. He received a Master's degree in geology from the University of Michigan in 1956 and a Ph.D. from Indiana University in 1959. His dissertation led to an interest in probability and statistics and a postdoctoral fellowship in statistics at the University of Chicago.

Following several academic positions and 7 years at Gulf Research and Development Company, Richard took up a position with the USGS in the mid-1970s, where he spent the balance of his career, achieving the position of Chief of the Branch of Resource Analysis in 1992. He conducted research in assessment of mineral resources and application of numerical methods to mineral exploration.

Author or coauthor of more than 100 publications and technical reports, Richard was an early user of cluster analysis and other multivariate methods for purposes of classification in the 1960s, when these methods were first being applied to geological problems. His research reports and papers at the USGS addressed numerical methods for estimating number and size of undiscovered mineral resources in a region.

His activities in the IAMG include serving as Western Treasurer, 1980–1984; Secretary General, 1984–1989; President, 1989–1992; and Past President 1992–1994. He was the second Editor in Chief for *Mathematical Geology* (now *Mathematical Geosciences*), serving in that capacity from 1976–1980. He negotiated with a publisher for works too long for journals, resulting in the *Monograph Series in Mathematical Geology* (now *Studies in Mathematical Geosciences*), which he edited 1987–1998. His interest in founding a journal dedicated to the appraisal of natural resources led him to again work with a publisher to create *Nonrenewable Resources* (now *Natural Resources Research*) and serve as its first editor in chief, 1992–1998.

In recognition for his research contributions, service to the profession, and service to the IAMG, Richard B. McCammon received the prestigious Krumbein Medal in 1992.

Acknowledgments I obtained personal, academic, and career details from Ricardo Olea's biography of Richard McCammon (*Mathematical Geology*, Vol. 27, p. 463). The IAMG website (www.iamg.org) lists his terms as an IAMG officer and editor. I would like to thank Frits Agterberg for confirming that Richard was present at the inaugural meeting in Prague, Czech Republic, in 1968; and B. S. Daya Sagar for providing the photograph.

Membership Functions

Candan Gokceoglu

Department of Geological Engineering, Hacettepe University, Ankara, Turkey

Definition

Unlike the classical set theory, the transitions in a universe can be smooth, and the definitions of elements can be mixed and diversified with the help of membership definitions of a given set. An element defined with fuzzy sets can be members of different classes, which ensure the gradual transition between them. The fuzzy sets can unfold and model the vagueness and the uncertainty in the universe by designing various degrees of memberships at the boundaries. Hence, a function needs to be designed for defining the memberships of the elements, and

these functions are defined as membership functions. Figure 1 shows a general difference between characteristic function for crisp set A and membership function for fuzzy set A.

Introduction

A fuzzy set is a class of object with a continuum of grades of membership, and such a set is characterized by a membership function which assigns to each object a grade of membership ranging between 0 and 1 (Zadeh 1965). Modeling has become an important research problem in Earth Sciences due to the development of data collection and processing methods in the last few decades. However, the models utilized in Earth Sciences are extremely complex, since they deal with natural events and processes. In addition, it is clear that expressing the elements employed in a model as crisp sets would not be adequate to eliminate the uncertainty. Instead, expressing each element with a degree of membership will decrease the uncertainty and yield to more representative models. Therefore, the use of membership functions in modeling problems in Earth Sciences has a significant contribution for addressing the natural phenomena or processes properly.

Mapping is an important concept in relating set-theoretic forms to function-theoretic representations of information (Ross 2004). The main characteristics of membership functions were described by Dombi (1990). According to the membership function properties described by Dombi (1990), all membership functions are continuous, and all membership functions map an interval $[a, b]$ to $[0, 1]$, $\mu[a, b] \rightarrow [0, 1]$. In addition, the membership functions are either increasing or decreasing monotonically or can be divided into a monotonically increasing or decreasing part (Dombi 1990). The monotonous membership functions on the whole interval are either convex functions or concave functions, or there exists a point c in the interval $[a, b]$ such that $[a, c]$ is convex and $[c, b]$ is concave (called S-shaped functions) (Dombi 1990). Another property of membership functions is that monotonically increasing functions have the property $u(a) = 0$, $u(b) = 1$, while monotonically decreasing functions have the property $u(a) = 1$, $u(b) = 0$ (Dombi 1990). Finally, the linear form or linearization of the membership function is important (Dombi 1990). Figure 2 shows the general properties of a trapezoidal membership function.

As can be seen from Fig. 2, the “core” of a membership function for a fuzzy set A is defined as the region of a universe that is characterized by a complete and full membership in the set A, and hence, the core comprises those elements x of the universe such that $\mu_A(x) = 1$. The “support” of a membership function for some fuzzy set A is defined as that region of the universe that is characterized by nonzero membership

Membership Functions,

Fig. 1 General view of a characteristic function for a crisp set and membership function for a fuzzy set. (Rearranged after Berkan and Trubatch (1997))

Membership Functions, Fig. 2 General properties of a membership function. (Rearranged after Ross (2004))

in the set A, and it means that the support comprises those elements x of the universe such that $\mu_A(x) > 0$ (Ross 2004).

Types of Membership Functions

In this entry, the most common forms of membership functions are presented. The most commonly used membership functions are singleton, Gaussian, generalized bell, sigmoidal, and triangular and trapezoidal membership functions (Rutkowski 2004). Their mathematical descriptions are provided below.

- (i) “Singleton membership function” is defined as unity at a particular point and zero everywhere else.

$$\mu(x) = \begin{cases} 1 & \text{for } x = \bar{x} \\ 0 & \text{for } x \neq \bar{x} \end{cases}$$

- (ii) “Gaussian membership function” is controlled by two parameters such as $\bar{x}$ (controls the center) and σ (controls the width).

$$\mu(x) = \exp\left(-\left(\frac{x - \bar{x}}{\sigma}\right)^2\right)$$

- (iii) “Generalized bell membership function” is governed by three parameters. These are a (responsible for its width), c (responsible for its center), and b (responsible for its slopes).

$$\mu(x) = \frac{1}{1 + \left|\frac{x-c}{a}\right|^{2b}}$$

- (iv) “Sigmoidal membership function” is controlled by two parameters such as a (controls for its slope) at the cross-over point $x = c$.

$$\mu(x) = \frac{1}{1 + \exp[-a(x - c)]}$$

- (v) “Triangular membership function” is completely controlled by three parameters such as a , b , and c ; and $a < b < c$.

$$\mu(x) = \max\left(\min\left(\frac{x-a}{b-a}, \frac{c-a}{c-b}\right), 0\right)$$

- (vi) “Trapezoidal membership function” is controlled by four parameters such as a , b , c , and d ; and $a < b < c < d$.

$$\mu(x) = \max\left(\min\left(\frac{x-a}{b-a}, 1, \frac{d-x}{d-c}\right), 0\right)$$

The representative views of the membership functions mentioned above are given in Fig. 3.

Use of Membership Functions in Earth Sciences

When the materials are natural rock, the only known fact about the certainty is that this material can never be known

Membership Functions,**Fig. 3** Graphical form of the most commonly used membership functions

with certainty (Goodman 1995). This idea is valid for all natural materials, events, and processes. For this reason, classifying natural materials or explaining the natural processes involves uncertainty at different levels. Although the issue of uncertainty (historic, present, or future) is often mentioned, it is mostly as a side note, and it is still rarely used for quantitative and predictive purposes (Caers 2011). In the recent two decades, various fuzzy and neuro-fuzzy modeling studies for classification and prediction problems in Earth Sciences have been demonstrated, and all the models have membership functions. In fact, the features of membership functions fit the classification and prediction of events and processes in Earth Sciences. One of the pioneering fuzzy studies was performed by den Hartog et al. (1997) for the performance prediction of a rock-cutting trencher, in which trapezoidal membership functions were used. Subsequently, several studies in the international literature of the Earth Sciences have been published. Prediction of susceptible zones to landsliding (Akgun et al. 2012) and the prediction of rockburst (Adoko et al. 2013) can be listed as examples for such studies. Akgun et al. (2012) used trapezoidal and triangular membership functions, while Adoko et al. (2013) employed Gaussian

membership functions. The type of membership functions depends on the nature of problem, and the membership functions can be created based on expert opinion or by using data-driven approaches.

Summary or Conclusions

This entry presents the definition of membership functions with examples to their types commonly used in Earth Sciences. Due to the complexity of natural events or processes, it is not an easy task to classify natural materials and define their properties, and to predict natural events by employing crisp classes and sets. Due to this reason, the solutions proposed for such problems have uncertainty. To minimize the uncertainty, fuzzy sets including membership functions have been used in real-world problems. Use of expert opinion is one of the major advantages of membership functions because representative and reliable data cannot be obtained each time to solve the problems in Earth Sciences. In addition, the membership functions provide a flexible and transparent tool for many inference systems.

Merriam, Daniel F.

D. Collins

Emeritus Associate Scientist, The University of Kansas,
Lawrence, KS, USA

Fig. 1 Dan Merriam (© public domain)

Biography

Daniel (Dan) Francis Merriam (1927–2017) is known as one of the leading pioneers of mathematical geology and one of the foremost exponents of computer applications in the geosciences.

Following distinguished service with the US Navy in the Pacific in World War II, Dan's professional development began at the University of Kansas where he received an undergraduate degree in geology in 1949. Following 2 years of field work with Union Oil, Dan took a job with the Kansas Geological Survey (KGS) at the University of Kansas and enrolled in graduate school, receiving his MS degree in geology in 1953 and his PhD in 1961. He subsequently received the M.Sc. degree (1969) and D.Sc. degree (1975) from Leicester University, England.

Dan became the Survey's Chief of Geologic Research in 1963, where his promotion of quantitative analysis of geologic data began in earnest. With Dan as editor of the Survey's *Special Distribution Series* (1964–1966), numerous papers on quantitative analysis were published with computer programs in ALGOL, BALGOL, and FORTRAN II. Dan then served as editor of the KGS series *Computer Contributions*, an irregular publication of 50 issues (1966–1970) with computer programs for analysis of geologic data (available online at www.kgs.ku.edu). In 1969, while at the KGS, Dan also became the editor for the new Plenum Press series, *Computer Applications in the Earth Sciences*.

During the dramatic events of the Prague Spring in 1968, Dan participated as a founding member of the International Association for Mathematical Geology (IAMG - now International Association for Mathematical Geosciences). This led to Dan's creation of IAMG's international journals, *Mathematical Geology* (now *Mathematical Geosciences*) in 1969 and, with Elsevier, *Computers & Geosciences* in 1975, both edited by Dan for many years. He also edited another IAMG journal, *Natural Resources Research*, starting in 1999. In addition, Dan edited 11 books and published more than 100 papers during his career.

Dan was elected Secretary General of IAMG in 1972 and President in 1978. Among his many awards and distinctions, IAMG presented Dan the sixth William Christian Krumbein Medal (1981) for his scientific contributions and support of the geologic profession in general and the IAMG in particular (Davis 1982). The Geologic Society (London) presented him with the William Smith Medal in 1992.

In 1971, Dan moved to Syracuse University as Chairman of the Department of Geology. With Dan's leadership, Syracuse University became known as a leading center for quantitative studies in the geosciences. In 1981, Dan accepted a position as Chairman of the Department of Geology at Wichita State University in Kansas, where he stayed until 1991 when he rejoined the KGS in Lawrence, Kansas. Retiring in

1997, Dan remained active as an Emeritus Scientist for most of the last two decades of his life.

Metadata

Simon J. D. Cox
CSIRO, Melbourne, VIC, Australia

Definition

Metadata is information about a data resource or transaction. Metadata provides contextual and summary information about a dataset or data item. Metadata may be useful in discovery, selection, management, access, and use of the described resources.

Metadata Standards

Metadata refers to information *about* other data, as distinct from information embodied *within* it. While descriptive records may be constructed for a wide variety of resources, including services, processes, and physical objects, those relating to **data and datasets** are often denoted **metadata**. Private metadata is created and stored as a routine process in data management systems. However, for external or public use, standard metadata structures and formats should be used.

Libraries

Libraries and archives had a long-standing practice of summary descriptions of the “information resources” which they manage, for example, in the form of index cards in a

catalogue. Metadata for books was standardized through Cataloguing-in-Publication records to be prepared by publishers, the MARC standards from Library of Congress, and in the context of library management software developed by organizations such as OCLC, alongside local and disciplinary standards. These practices had a strong influence on the development of “generic” metadata standards through the **Dublin Core** Metadata Initiative (Kunze and Baker 2007; DCMI Usage Board 2020), which emerged in the web era, but have been influential quite broadly and are used directly in many metadata records and systems. Dublin Core now includes nearly 80 terms, but the classic 15 terms, which are most widely used, indicate the overall scope.

Dublin core element	Key application(s)
Title	Discovery and selection
Description	Discovery and selection
Subject	Discovery and selection
Coverage (<i>spatial and temporal scope</i>)	Discovery and selection
Language	Discovery and selection, use
Type	Discovery and selection, management
Identifier	Management, access
Creator, contributor, and publisher	Management, provenance
Date	Provenance, discovery, and selection
Format	Access, use
License, rights	Access, use
Relation	Discovery and selection, provenance

Web Pages

Metadata also appears in web pages, where it may be used for web search indexing. Several of the most prominent search systems sponsored the development of a more comprehensive set of metadata tags in **Schema.org** (Guha et al. 2015). This is maintained through an open community process. Schema.org now includes hundreds of elements, though only a subset of these are used for the general-purpose indexes. However, a profile known as **Science-on-Schema.org** has been developed by the earth and environmental science community and is published and harvested in some specialized indexes (Jones et al. 2021).

Geospatial

Much geoscience data is georeferenced. Geospatial metadata standards were originally developed somewhat

Metadata, Fig. 1 The DCAT metadata model, showing relationships between datasets, dataset-series, data-services, and catalog entries

independently, driven by requirements of map and image libraries, which were influenced by rapid growth of non-proprietary remote sensing data. Important general geospatial metadata standards were designed by the US Federal Geographic Data Committee (FGDC), and the Australia and New Zealand Land Information Council (ANZLIC). These were consolidated and standardized internationally as ISO 19115 (ISO/TC 211 2014, 2016, 2019). Data discovery systems based on these ISO standards are available from many statutory data providers in the Geosciences (e.g., geological surveys).

Semantic Web

The W3C's Resource Description Framework (RDF) provides a generic platform for metadata, which enables component vocabularies that have been defined for various concerns to be mixed and matched as required. For example, there are W3C-conformant vocabularies covering a number of specific concerns as follows:

Vocabulary	Concern	Reference
SKOS	Organizing keywords and classifications	Isaac and Summers (2009)
DQV	Data quality	Albertoni and Isaac (2016)
ODRL	Rights and licensing	Iannella et al. (2018)
PROV-O	Provenance	Lebo et al. (2013)

(continued)

Vocabulary	Concern	Reference
GeoSPARQL	Geospatial descriptions	Perry and Herring (2012)
OWL-Time	Temporal descriptions	Cox and Little (2017)

The Data Catalog Vocabulary (Albertoni et al. 2020) combines these with Dublin Core to cover most of the concerns of a comprehensive metadata record for datasets and services, including geospatial (see Fig. 1 for a summary). The threads are brought together in GeoDCAT (Perego and van Nuffelen 2020), which is effectively an RDF implementation of the ISO 19115 Geospatial metadata standard, accomplished by using elements from many of these vocabularies.

Keywords and Controlled Vocabularies

Metadata for geoscience data usually includes keywords and classifiers from domain specific vocabularies, such as minerals, lithology, the geological timescale, and taxonomic references, as well as lists of procedures, sensors, software, and algorithms that may have been used in the production of a dataset (i.e., data provenance), and therefore be important in discovery and selection of datasets by potential users. Geoscience vocabularies are provided by agencies such as geological surveys. Maximum interoperability and transparency are achieved by the use of FAIR vocabularies, where each term or vocabulary item is denoted by a unique, persistent web identifier or IRI (Wilkinson et al. 2016).

Summary

Metadata describes datasets in order to support a number of functions, including finding, selecting, accessing, using, and managing data. Metadata intended for public use should follow standards. Specialist geospatial metadata standards are used by many agencies and data repositories, while general metadata standards have been developed by the web community.

Mine Planning

N. Caciagli
Metals Exploration, BHP Ltd, Toronto, ON, Canada
Barrick Gold Corp, Toronto, ON, USA

Synonyms

Mine design

Definition

Mine planning encompasses the design and implementation of safe, sustainable, and profitable plans for mining operations, with the aim of maximizing value.

Introduction

The extraction of natural resources is fundamental to modern society. Almost everything we touch and use has some component that was mined. However, the ore bodies that are being discovered are increasingly lower grade and more difficult to mine. Additionally, the social and environmental impacts to mining need to be addressed and in many jurisdictions are becoming more regulated. As a result, the extraction and processing methods must become more intricate and the planning process and models more detailed and robust.

Inputs into Mine Planning

Inputs into the mine planning process include:

- Orebody characteristics contained within geological, geo-technical, and geometallurgical models
- Mining method and layouts, taking into account the local mining and environmental regulations regarding safety, noise, dust, and other impacts to workers and the environment
- Technical inputs such as cut-off grades and requirements for blending or stockpiling
- Operational inputs such as ore loss and dilution factors, mining, and processing costs
- Processing plant capacity and feed requirements
- Final product requirements and specifications (e.g., penalty element content)
- Commodity value based on both short- and long-range forecasting

Much of the mine planning process aims to generate to a set of high-level options around these inputs, building several hypothetical models or plans to be tested to determine which plan yields the highest value (Whittle 2011). Any one of the inputs or decisions can affect all the others; for example, constraints around the processing method will affect the optimum cut-off grades, changes in cut-off grade will affect the mining schedules, and changes in schedules affect which pit shells or mine levels should be selected as mine phases. A change in the commodity price will affect everything, right back to the mine design (Whittle 2010). Additionally, mine planning has the added dimension of time and needs to consider when and how each phase or structure is implemented.

Mine planning examines specific problems at different stages of the mining value chain and can be broken down into three views to better address these:

- Long-term mine planning
- Medium-term mine planning
- Short-term mine planning

Long-term mine planning aims to define the “best” mine plan over the full life of mine, subject to the constraints imposed by physical and geological conditions, as well as corporate and regulatory policies. The term “best” is typically defined as maximizing the monetary value and guarantying a safe operation but also includes quality characteristics of the product extracted and delivered (Goodfellow and Dimitrakopoulos 2017). Long-term mine planning also considers capital investment decisions, sovereign risk issues as well as market demands for the material to be mined.

Medium-term mine planning focuses on issues such as mobile equipment capital investment, strategic positioning for optimization of product quality, and processing plant

capacity. This also considers stope access or drift development for underground mines or pit phases and pushbacks for open pit mines.

Short-term mine planning focuses on production scheduling. Where to mine next week, is it accessible? Is there enough blasted inventory to feed the crusher and the plant?

Methodology and Tools

Most commercial open pit mine planning tools use a Nested-Pit methodology based on the Lerchs and Grossmann algorithm (Lerchs and Grossmann 1965). The Lerchs-Grossmann algorithm determines the economic three-dimensional shape of the pit considering block grades, pit slopes, costs, recoveries, and metal prices and is based on the valuation of each block in the model. Also known as the Nested Pit method this procedure breaks down the problem into two parts: it determines a set of push-packs (or phases) to be used as guides to construct a production schedule and then schedules the blocks in each push-back, bench by bench.

Underground mine planning has no equivalent methodology for determining an “ultimate pit limit,” rather the models or plans to be tested and assessed focus on the on the choice of “best” mining method (e.g., stoping or caving methods), development and layout of infrastructure, design of stope boundaries or envelopes, and production scheduling. For underground mining there are a few optimization algorithms developed in the 1990s and early 2000s. Alford (1995) developed the heuristic floating stope algorithm to define the optimum stope envelopes, analogous to the floating cone algorithm used in open pit optimization. Others have presented variants on the heuristic method first proposed by Alford utilizing a maximum value neighborhood (MVN) heuristic algorithm, integer programming techniques, or 3D modeling (Musingwini 2016 and references therein). Other work has focused on selecting optimal mining methods or planning mine development and layout using neural networks or genetic algorithms (Newman 2010 and references therein). However, a method to integrate the layout and development planning, sizing of stope envelopes, production scheduling, equipment selection, and utilization with the aim to enable just-in-time development analogous to open-pit planning remains elusive.

It is understood that the uncertainties associated with the input parameters, especially metal grades or commodity prices, can lead to large deviations from expected budgets. However, accounting for these in mine planning remains an active area of research and development (Musingwini 2016 and references therein, Newman et al. 2010 and references therein, Davis and Newman 2008 CRC mining conference).

Sources of Uncertainty

Orebody characterization attempts to quantify the sources of uncertainty that contribute most to the differences between planned and operational outcomes. Geological uncertainty represents the level of confidence in the mineralogical characterization, grade, continuity, as well as of the extent and position of geological units. Resource model estimates are continuous interpolations of discretely obtained data, but the models do not capture the real variability of the deposit and tend to reduce the variability of the deposit attributes (Jélvez et al. 2020; Goodfellow and Dimitrakopoulos 2017) which in turn leads to cascading impacts within the mine planning outputs.

Accounting for these uncertainties allows for the development of models that are more realistic and creates the opportunity to develop options within the mine plan (Davis and Newman 2008 CRC mining conference).

Jélvez et al. (2020) looked at incorporating uncertainty into the mine planning process by representing geological uncertainty as a series of stochastic simulations of the block model. This methodology developed strategies for the definition of the ultimate pit limit, pushback selection, and production scheduling.

Goodfellow and Dimitrakopoulos (2017) implemented a stochastic approach to optimizing the entire mining complex incorporating the variability of materials and metal content into the simultaneous production scheduling, ore dispatching, and processing (stockpiling or blending) decision variables.

In both case studies a stochastic design is better able to meet the production targets and simultaneously reduce the risk in production profiles and increase the expected NPV, highlighting the importance of characterizing uncertainty and incorporating it into mine planning work.

Conclusions

Mining has become more challenging given the nature of the orebodies being discovered, health, safety, and environmental requirements and the sophisticated extraction and processing methods available. This has demanded the mine planning process solve increasingly more complex problems and necessitating more intricate and integrated solutions.

Mineral Prospectivity Analysis

Emmanuel John M. Carranza

Department of Geology, Faculty of Natural and Agricultural Sciences, University of the Free State, Bloemfontein, Republic of South Africa

Definition

The phrase “mineral prospectivity” denotes the probability or chance that mineral deposits of a certain class can be discovered in an area because the geology of this area is permissive or favorable to the formation of such class of mineral deposits. The phrase is synonymous to the phrase “mineral favorability” or “mineral potential,” either of which denotes the possibility or likelihood that a certain class of mineral deposits exist in an area because the geology of this area is permissive or favorable to the formation of such class of mineral deposits. However, the phrase “mineral prospectivity” is used in this encyclopedia because the term “prospectivity” relates to the search, prospecting, or exploration of mineral deposits of economic importance. Mineral prospectivity analysis, therefore, aims to predict where undiscovered mineral deposits of a certain class exist in order guide mineral exploration.

Introduction

Because the occurrence of any mineral deposit is revealed by the existence of certain pieces of geological evidence (for example, abnormal concentrations of certain metals in certain earth materials), mineral prospectivity is associated to the amount of geological evidence. Therefore, as shown in Fig. 1, mineral prospectivity analysis dwells on two assumptions. First, an area is prospective if it is typified by pieces or layers of geological evidence that are the same or similar to those in areas where mineral deposits of a certain class exist. Second, if in one area there exist more pieces or layers of geological evidence than in another area in a geologically permissive or favorable terrane, then the degree of mineral prospectivity in the first area is higher than in the second area.

Mineral prospectivity analysis can be linked to every or any stage of mineral exploration, from broad regional-scale to

restricted local-scale, whereby it involves analysis and synthesis of pieces or layers of evidence, in map form, obtained from spatial data of different geoscientific types (e.g., geophysical, geological, and geochemical). The purpose of that is to outline exploration targets (Fig. 1) and to prioritize such targets for exploration of yet to be discovered mineral deposits of the class of interest. On a regional-scale, mineral prospectivity analysis endeavors to outline exploration targets within continental-scale geologically permissive regions; on district- to local-scales, mineral prospectivity analysis seeks to delineate exploration targets in more detail. These imply that the spatial resolution, detail, accuracy, and information content of individual sets of geoscientific data, as well as understanding of mineral deposit occurrence, employed in mineral prospectivity analysis for exploration targeting must increase progressively from regional- to local-scale.

Mineral Prospectivity Analysis,

Fig. 1 Level of mineral prospectivity is correlated with level of spatial coincidence of relevant layers of evidence. Areas with the same or similar level of mineral prospectivity as existing mineral deposits (triangles) are regarded as exploration targets

Conceptual Modeling of Mineral Prospectivity

The analysis of mineral prospectivity should relate to mineral deposits of a single class or related mineral deposit belonging to a single mineral system. Therefore, a map of mineral prospectivity for porphyry Cu deposits is not appropriate for guiding exploration for diamond deposits, or the other way around. At every scale of exploration targeting, however, mineral prospectivity analysis adheres to definite steps commencing with the conceptualization of prospectivity for mineral deposit class or mineral system of interest (Fig. 2). Theoretical and spatial relationships among various features, which are factors or controls on how and where mineral deposit of a certain class forms, comprise the mineral prospectivity conceptual model. This model prescribes in expressions and/or illustrations of the theoretical or hypothetical interplays among different geological processes in the measure of how and particularly where mineral deposits of the class of interest possibly form.

Conceptualization of prospectivity for mineral deposits in an area needs a thorough review of literature on characteristics and processes of formation of mineral deposits of the class of interest, such as described in mineral deposit models (e.g., Cox and Singer 1986). A robust mineral prospectivity conceptual model is one that also adheres particularly to the mineral systems approach to exploration targeting. This approach focuses on three main themes of geological elements (or processes) that are critical to the formation of mineral deposits (Walshe et al. 2005; McCuaig et al. 2010): (a) source of metals; (b) pathways for metal-bearing fluids; and (c) depositional traps. Analysis of the spatial distribution of mineral deposits of the class of interest in an area and analysis of the spatial relationships of such mineral deposits with certain geological features in the same area can provide supplementary knowledge to the conceptualization of prospectivity for mineral deposits (Carranza 2009).

The spatial (geophysical, geological, and geochemical) features of known mineral deposits of the class of interest, whether they exist in the area currently being explored or in

other areas with similar geological setting, comprise the criteria for recognition or modeling of prospectivity. These criteria and the mineral prospectivity conceptual model instruct the structure of mineral prospectivity analysis with regard to the choice of appropriate of the following:

- Sets of geoscientific spatial data to be employed.
- Evidential elements to be mapped from each set of geoscientific spatial data.
- Techniques for converting each map of evidential elements into a map of prospectivity recognition criterion.
- Techniques for weighting of each class or range of values in a map of prospectivity recognition criterion to generate a predictor map.
- Techniques of combining predictor maps to generate a mineral prospectivity map.

The items (b), (c), and (d) pertain to the analysis of mineral prospectivity parameters.

Preparation of Evidence Maps

A map that portrays a prospectivity recognition criterion is called an evidential map, or in Geographic Information System parlance, an evidential layer. Techniques for mapping evidential elements expressive of a criterion of mineral prospectivity are explicit to types of geoscientific spatial data (i.e., geophysical, geological, and geochemical). Concepts of mapping of anomalies from geochemical data for mineral exploration are discussed in the chapter for Exploration Geochemistry. Geological elements of specific classes of mineral deposits, such as hydrothermal alterations, are detectable and mappable by remote sensing (see chapters on Hyperspectral Remote Sensing, Mathematical Methods in Remote Sensing Data and Image Analysis, Remote Sensing). Geological elements such as structures or rock units considered as proxies of controls of mineral deposit formation can be extracted from

Mineral Prospectivity Analysis,

Fig. 2 Components of mineral prospectivity analysis. Solid arrows portray input-output workflow. Dashed arrows denote support among or feedback between components

existing geological maps or mapped from images of suitable geophysical data (e.g., Kearey et al. 2002).

Some geoscientific spatial data or some types of mapped evidential elements must be manipulated or transformed in order to portray them as evidential maps. The choice of technique to manipulate or transform specific relevant data, to generate an evidential map, depends on which criterion for recognition of prospectivity is to be represented. For example, representation of fluid pathways as a control on mineral deposit formation first needs extraction of certain structures from a spatial database, then generation of a map of distances to such structures, and finally classification of distances into ranges of proximity. This manipulation or transformation is generally known as buffering (see chapter on Geographic Information System). Similarly, representation of chemical traps as a control of mineral deposit formation may first need appropriate interpolation of metal concentration data at sample locations and then classification of the interpolated metal data into different levels of presence of chemical traps. For concepts of methods of interpolation, see chapters on Interpolation, Inverse Weighted Distance, or Kriging. Classification is also a typical operation in a Geographic Information System. The purpose of manipulation or transformation of a map of evidential elements or image of relevant spatial data to generate an evidential map is to represent the degree of presence of evidential elements per location.

Generation and Integration of Predictor Maps

Techniques for the assignment of weights to each class or range of values in an evidential map, in order to generate a predictor map, involve either data- or knowledge-driven analysis of their spatial relationships with discovered mineral deposits of the class of interest (Carranza 2008). On the one hand, data-driven techniques quantify spatial relationships between a mineral deposit location map and each class or range of values in an evidential map; quantified degrees of spatial relationship translate to weights of each class or range of values in an evidential map. On the other hand, knowledge-driven techniques make use of expert opinions to assign weights to each class or range of values in an evidential map. Not every technique for data-driven quantification of spatial relationships between a mineral deposit location map and an evidential map steers can be used for the generation and then combination of predictor maps to obtain a predictive mineral prospectivity map. Data-driven techniques that only quantify spatial relationships between classes or range of values in an evidential map are those that are useful in providing supplementary knowledge to the conceptualization of prospectivity for mineral deposits as mentioned above. In contrast, every technique for knowledge-driven predictor map generation can be used straight away for predictor map

combination to generate a predictive mineral prospectivity map.

Therefore, mineral prospectivity analysis is either data- or knowledge-driven. The main distinction between data- and knowledge-driven mineral prospectivity analyses lies in the generation of predictor maps. Data-driven mineral prospectivity analysis uses known mineral deposits to assign (i.e., quantify) weights to each class or range of values in an evidential map. Knowledge-driven mineral prospectivity analysis uses expert opinion to assign (i.e., qualify) weights to each class or range of values in an evidential map. Data-driven mineral prospectivity analysis is suitable in moderately to well-explored geologically permissive areas (also known as “brownfields”) where several mineral deposits of the class of interest exist. Knowledge-driven mineral prospectivity analysis is suitable in less-explored geologically permissive areas (also known as “greenfields”) where no or very few mineral deposits of the class of interest are known to exist. In either case, a predictive mineral prospectivity map is generated by integrating at least two predictor maps (Fig. 1) using a mathematical (e.g., probability, likelihood, favorability, or belief) function that appropriately represents or models the interplays among geological processes, represented by each predictor map that leads to mineral deposit occurrence or formation, thus: *predictive mineral prospectivity map* = $f(\text{predictor maps})$. The mathematical function f used typically in mineral prospectivity analysis conveys empirical interactions among predictor maps (as proxies of factors or controls) of mineral deposit occurrence. On the one hand, knowledge-driven techniques of mineral prospectivity analysis commonly make use of logical functions (e.g., AND and/or OR operators; see Fuzzy Set Theory) for successive combination of predictor maps guided by an inference system (Fig. 3). On the other hand, data-driven techniques of mineral prospectivity analysis commonly make use of mathematical functions for instantaneous combination of predictor maps irrespective of knowledge on the interplays of geological factors or controls of mineral deposit occurrence. A few data-driven techniques use functions signifying logical operations (e.g., Dempster’s rule of integrating belief functions; see Carranza et al. 2008) successive combination of predictor maps guided by an inference system. Similarly, a few knowledge-driven techniques use mathematical (mainly arithmetic or logical) functions for instantaneous combination of predictor maps.

For mineral prospectivity analysis, the most commonly used data-driven technique is weight-of-evidence analysis, and the most commonly used knowledge-driven technique involves the application of the fuzzy set theory (for details, see Bonham-Carter 1994). Most published researches on mineral prospectivity analysis can be found in the following journal: Natural Resources Research, Ore Geology Reviews, Mathematical Geosciences and Computers & Geosciences.

Mineral Prospectivity Analysis,

Fig. 3 Example of inference system using suitable logical functions (e.g., AND and/or OR operators, etc.) for successive combination of predictor maps through knowledge-driven mineral prospectivity analysis. An inference system portrays an analyst's understanding or an expert's opinion of the interplays of geological factors or controls of mineral deposit occurrence

Evaluation of Results of Mineral Prospectivity Analysis

Every technique of mineral prospectivity analysis produces *systemic* (or procedure-related) errors vis-à-vis the interplays of geological factors or controls of mineral deposit occurrence. Moreover, each set of geoscientific spatial data or each evidential map employed in mineral prospectivity analysis usually carries *parametric* (or data-related) errors vis-à-vis the spatial distribution of mineral deposits. Because these types of errors are unavoidable in mineral prospectivity analysis and because they spread from input data to evidential map to predictor map to final output mineral prospectivity map, it is necessary to employ strategies for predictive map evaluation and, if needed, to reduce error in each step of mineral prospectivity analysis. The ideal strategy to evaluate the predictive capacity of a mineral prospectivity map is, of course, to use it as basis for guiding mineral exploration and hope that it leads to mineral deposit discovery. However, this is not a practical strategy because it usually takes several years before a mineral deposit is discovered through grassroots exploration.

A practical way to evaluate results of mineral prospectivity analysis is to answer the following question. For at least two predictive mineral prospectivity maps (say, generated by different techniques or generated by the same techniques but using different parameters), which map (a) delineates the smallest proportion of prospective areas but (b) contains the largest proportion of existing mineral deposits of the class of interest? To answer and visualize the answer to this question, one must create a so-called *area-occurrence plot* per mineral prospectivity map (Fig. 4) (Agterberg and Bonham-Carter

2005). This question is relevant to results of either data- or knowledge-driven mineral prospectivity analysis.

For knowledge-driven mineral prospectivity analysis, the area-occurrence plot is appropriately called a *prediction-rate* plot because mineral deposits are not used to create predictor maps (i.e., assign weights to each class or range of values in an evidential map). Therefore, according to Fig. 4, the map based on mineral prospectivity model 1 has greater predictive capacity than the map based on mineral prospectivity model 2. For example, considering predicted prospective areas occupying 10% of a region, the predictive capacity of mineral prospectivity model 1 is about 75% whereas that of mineral prospectivity model 2 is just about 45%.

For data-driven mineral prospectivity analysis in which all existing mineral deposits are used to create predictor maps, the area-occurrence plot is appropriately a *success-rate* plot. That is, the success-rate plot portrays only the goodness-of-fit between evidential maps and the map of mineral deposits locations used for calculating the weights for each class or range of values in each evidential map. Therefore, according to Fig. 4, the map based on mineral prospectivity model 1 has greater goodness-of-fit with the mineral deposits based on which it was created compared to the map based on mineral prospectivity model 2.

To determine the predictive capacity of a data-driven mineral prospectivity model, one must answer the following question: Assume that, for a study area, we split the existing mineral deposits of the class of interest into two sets. The first set, called the *training set*, is used in mineral prospectivity analysis. What proportion of the second set, called the *validation set* (i.e., mineral deposits presumed to be undiscovered), coincides spatially with high prospectivity

Mineral Prospectivity Analysis, Fig. 4 Area-occurrence plots for evaluation of mineral prospectivity models. The procedure for creating such plots involves a series of delineation of prospective areas in a mineral prospectivity map using decreasing threshold values at narrow, say 5-percentile, intervals from the highest to the lowest prospectivity values, which yield, respectively, the lowest and the highest proportions of prospective areas. Then, the next step is to determine the cumulative increasing proportions of existing mineral deposits contained in

respective cumulative increasing prospective areas defined by decreasing prospectivity values. Finally, proportions of contained mineral deposits are plotted on the y-axis, and proportions of prospective areas are plotted on the x-axis. The gauge line represents a random spatial relationship between mineral deposits and prospectivity values in a mineral prospectivity map. For a mineral prospectivity map, the higher above its occurrence-area plot is relative to the gauge line, the stronger is its predictive capacity

values derived from the first set? This question is the principle of blind testing of data-driven mineral prospectivity analysis (cf. Fabbri and Chung 2008). It applies to evaluation of mineral prospectivity analyses using one technique or different techniques. Similarly, to answer and visualize the answer to this question, one must create a so-called *area-occurrence plot* per mineral prospectivity map. Moreover, the role of the first and second sets of mineral deposits can be switched to compare the predictive capacities of two mineral prospectivity models using the same technique of mineral prospectivity analysis. In this case, the area-occurrence plot is appropriately called a *prediction-rate* plot; therefore, according to Fig. 4, the map based on mineral prospectivity model 1 has greater predictive capacity than the map based on mineral prospectivity model 2.

Conclusions

A predictive mineral prospectivity map is generally an empirical model, portraying the chance of finding undiscovered mineral deposits of the class of interest. This is a critical

spatial information for management of mineral exploration. The routines in mineral prospectivity analysis can be tedious and complex, but nowadays these are facilitated with use of a Geographic Information System. However, mineral prospectivity analysis is a typical “garbage in, garbage out” activity because, as shown in Fig. 1, if the mineral prospectivity conceptual model is wrong, then the output mineral prospectivity map is wrong. Therefore, knowledge of how and where mineral deposits form is the most critical element of mineral prospectivity analysis. It is judicious to evaluate performance of mineral prospectivity maps before they are used to guide mineral exploration.

Minimum Entropy Deconvolution

Jaya Sreevalsan-Nair
Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

In reflection seismology, the reflected seismic waves are used to study the geophysical characteristics of the earth subsurface. Thus, in a seismogram model, deconvolution is routinely used to extract the earth reflectivity signal from a noisy seismic trace. The conventional method is used to whiten the spectra of the earth reflectivity signal, i.e., to assume that the signal has a constant value as the Fourier

transform. This, however, reconstructs only a part of the signal, as the assumption also implies that the signal is a Dirac delta function δ , i.e., a spiking function.

To adapt this method to include the practical characteristics of the signal of being noisy, band-limited, etc., minimum entropy deconvolution (MED) is used, where it finds the smallest number of the large spikes that are consistent with the data using minimum Wiggins' entropy measure (Wiggins 1978). MED was proposed by Wiggins in 1978, and MED has been inspired by the factor analysis techniques.

Overview

The seismic trace, x_t , that is measured has been observed to be a convolution between the earth reflectivity, y_t and a wavelet function, w_t . To obtain y_t , a straightforward signal processing process is to perform a deconvolution process, say using a linear scheme. However, in real life, the signal x_t tends to be contaminated with noisy signal, n_t . Thus, the normal incidence seismogram model is given by: $x_t = w_t * y_t + n_t$.

A filter f_t , which upon convolution with the wavelet function gives the Dirac delta function δ_t , is desired. Thus, $f_t * w_t = \delta_t$. However, the estimated filter $\hat{f}_t$ gives an averaging function, a_t , i.e., $\hat{f}_t * w_t = a_t$. Thus, to get the estimated reflectivity signal

$$\hat{y}_t = a_t * y_t + \hat{f}_t * n_t = y_t + (a_t - \delta_t) * y_t + \hat{f}_t * n_t.$$

The desirable solution is that the a_t is close to δ_t and n_t is relatively low. Given the band-pass nature of the seismic signals, only a part of the reflectivity signal is retrieved, i.e., the band-limited signal after removing the wavelet, $\hat{y}_t = y_t * a_t$. Thus, $\hat{y}_t$ and y_t are referred to as the band-limited and the full-band reflectivity signals. Estimating y_t from $\hat{y}_t$ is known to be a non-unique linear inverse problem. The Fourier transform gives $\hat{Y}_\omega = A_\omega \cdot Y_\omega$, for frequency ω . There are an infinite number of solutions for y_t that satisfies the Fourier transform equation, especially when $A_\omega \neq 0$.

MED has been proposed as a solution to reduce the non-uniqueness of the solution (Wiggins 1978) by finding those solutions which provide “minimum structure” to the reflectivity signal. The “minimum structure” is represented by “minimum entropy,” where entropy is proportional to the energy dispersal of the seismic signal. Entropy is also inversely proportional to normalized variance V . The difference between the traditional spiking deconvolution, i.e., predictive deconvolution, and MED is that the former whitens the signal, thus giving minimum normalized variance, whereas MED identifies isolated spikes, thus giving maximum normalized variance (Wiggins 1978).

Inspired by factor analysis techniques, the entropy term is given in terms of V of a vector $\mathbf{y}$ of reflection coefficients of length N , with amplitude-normalized reflectivity measure q'_i , and a monotonically increasing function $F(q'_i)$:

$$V(\mathbf{y}) = \frac{1}{N \cdot F(N)} \sum_{i=1}^N q'_i \cdot F(q'_i), \text{ where } q'_i = y_i^4 \cdot \left(\frac{1}{N} \cdot \sum_k y_k^2 \right)^{-1}.$$

Given this background (Sacchi et al. 1994), the following inequality holds: $\frac{F(1)}{F(N)} \leq V \leq 1$. Thus, the lower bound of V is when all the samples have equal value. The MED is obtained when $F(q'_i) = q'_i$, which is referred to as MED norm or Wiggins's entropy function. The original algorithm (Wiggins 1978) had used the varimax norm, given by $q'_i = \hat{y}_i^4 \cdot \left(\frac{1}{N} \cdot \sum_k y_k^2 \right)^{-2}$. To resolve the sensitivity of MED norm to strong reflections, other norms have been used, of which the logarithmic norm or the logarithm entropy function, i.e., $F(q'_i) = \ln(q'_i)$, has been found to be effective.

A trivial solution for the reflectivity signal y_t is $\hat{f}_t = x_t^{-1}$, $\hat{y}_t = \delta_t$, which requires inverting the seismic trace, which may not exist. Hence, a filter of fixed length (L) is applied to avoid the requirement of inverse computation. Thus, $y_n = \sum_{l=1}^L f_l \cdot x_{n-l}$.

Maximizing V implies $\frac{\partial V(\mathbf{y})}{\partial f_k} = 0$.

This optimization outputs a vector $\mathbf{b}$, with $b_i = G(q_i) y_i \cdot \left(\frac{1}{N} \sum_j G(q_j) q_j \right)^{-1}$. The final solution is solved using matrix system equation of $\mathbf{f} \cdot \mathbf{R} = \mathbf{g}(f)$, where $\mathbf{R}$ is the Toeplitz matrix of the input data, and the vector $\mathbf{g}(\mathbf{f})$ is the cross-correlation between $\mathbf{b}$ and x . Solving for the fixed length filter is achieved by using an iterative method, given by $\mathbf{f}^{(n)} = \mathbf{R}^{-1} \cdot \mathbf{g}(\mathbf{f}^{(n-1)})$ (Sacchi et al. 1994). In the original algorithm (Wiggins 1978), the reduction is $\mathbf{R} \cdot \mathbf{f} = \mathbf{g}$, where the matrix $\mathbf{R}$ is referred to as an autocorrelation matrix, that is a weighted sum of the autocorrelations of the input signals, and $\mathbf{g}$ is the weighted sum of the cross-correlations of the filter outputs cubed with the input signals. Each iteration involves solving the system using Levinson's algorithm and reproducing the features of the reflectivity signal. If the filter length L is chosen appropriately, the system maximizes V (Wiggins 1978).

A few significant improvements to the original MED method (Wiggins 1978) include the use of D norm instead of the varimax norm (Cabrelli 1984) and implementing the iterative solution in the frequency domain instead of the signal domain (Sacchi et al. 1994). The D norm is defined as $D(y) = \max_{1 \leq k \leq N} \frac{|y_k|}{\|\mathbf{y}\|}$, based on its equivalence to the geometrical interpretation of the varimax norm (Cabrelli 1984). Using MED with D norm, referred to as MEDD, has improved the signal-to-noise ratio of the outputs, and stability

in the presence of additive noise, when compared to MED. In a different kind of enhancement of MED using the varimax norm, the iterative solution is implemented in the frequency domain by minimizing the objective function Φ , which is the sum of the amplitudes of the signal values using a linear programming (LP) formulation (Sacchi et al. 1994). Using MED in the frequency domain, referred to as FMED, is an effective method for processing band-limited data. FMED additionally improves the estimation of higher frequencies compared to the original MED.

Applications

MED has been popularly used for seismic signal analysis in the 1980s and 1990s (Nose-Filho et al. 2018), after which the use of MED has increasingly shifted to applications outside of geophysics, e.g., speech signals (González et al. 1995) and early fault detection (EFD) in rotating machinery (Wei et al. 2019). In applications for seismic deconvolution, the predictive convolution and MED filters work with the single-input, single-output (SISO) systems, whereas the requirements have shifted to single-input, multiple-output (SIMO) systems (Nose-Filho et al. 2018). This shift has been required owing to the use of the common shot gather (CSG), which involves multiple receivers recording different shots from a single shot of the seismic wavelet. Thus, the analysis of SIMO seismic systems has paved the way to multichannel blind deconvolution (MBD) methods. Inspired by MED, sparse MBD (SMBD) accounts for sparsity in reflectivity signals.

As an example of extending MED to other forms of signals, it has been effectively used for period estimation of seismic signals, including natural, artificial, periodic, and quasiperiodic ECG and speech signals (González et al. 1995). MED has been effective and robust for individual period estimation.

Gear failure diagnosis involves analysis of vibration signals, where the quality of MED to identify signals with maximum kurtosis can be effectively used to deconvolve the impulsive sources in gear faults (Endo and Randall 2007). The existing autoregressive (AR) prediction method is used for detecting localized faults in gears, but owing to the use of autocorrelations, AR method is not sensitive to phase relationships. These relationships are necessary for differentiating noise from gear impulses. Since MED uses phase information in the form of kurtosis, MED in combination with AR filtering helps in detecting spalls and tooth fillet cracks in gears. This is an example of how MED is effectively introduced in a workflow of an application, entirely different from a seismic one.

MED has now been used in several such applications of combining with similar methods for EFD in rotating machinery (Wei et al. 2019). Analogous to the shift from SISO to SIMO systems in seismology, gear failure diagnosis uses

MED for solving the fault diagnosis for a single impulse as well as for an infinite impulse train (McDonald and Zhao 2017). Multi D norm, originally used in MEDD, has been used with an adjustment for EFD to generate non-iterative filters to be used on an infinite impulse train. This method is referred to as multipoint optimal MED adjusted (MOMEDA) method. MOMEDA has been further improved for complex working conditions by including product functions (Cai and Wang 2018). Thus, these examples demonstrate the potential of MED in providing stepping stones for improving analysis with increasing complexity in the problem. Another example of a combined method is where variational mode decomposition, L-Kurtosis, and MED are used in sequence for detecting mechanical faults, which have periodic impulses in the vibration signal (Liu and Xiang 2019).

Future Scope

In the recent past, MED has been effectively used in early fault diagnosis in mechanical systems. MED thus has the potential to work on applications involving impulse signals. Starting with seismological applications, MED has proved its mettle in identifying signals with minimum entropy or minimum structure since its inception (Wiggins 1978).

Minimum Maximum Autocorrelation Factors

U. Mueller

School of Science, Edith Cowan University, Joondalup, WA, Australia

Definition

Let $\mathbf{Z}(\mathbf{u}) = [Z_1(\mathbf{u}), Z_2(\mathbf{u}), \dots, Z_K(\mathbf{u})]$ be a K-dimensional random field on some region R in two- or three-dimensional space with covariance matrix Σ_0 and set of experimental semivariogram matrices $\{\Gamma(\mathbf{h}_i) : \mathbf{h}_i = i\mathbf{h}_0, \mathbf{h}_0 \in \mathbb{R}^2 (\mathbb{R}^3), i = 1, 2, \dots, \ell\}$ where $\mathbf{h}_0 \in \mathbb{R}^2 (\mathbb{R}^3)$ is fixed. The minimum/maximum autocorrelation factors $\mathbf{Y}$ of $\mathbf{X}$ are given by

$$\mathbf{Y}(\mathbf{u}) = \mathbf{Z}(\mathbf{u}) \Sigma_0^{-\frac{1}{2}} \mathbf{Q}$$

where $\mathbf{Q}$ is the matrix of eigenvectors of the covariance matrix $\mathbf{I} - \Sigma_0^{-\frac{1}{2}} \Gamma(\mathbf{h}_0) \Sigma_0^{-\frac{1}{2}}$ corresponding to $\mathbf{h}_0$ arranged so that the corresponding eigenvalues are decreasing in magnitude.

Introduction

Principal component analysis is a commonly used method of extracting the most relevant combinations from multivariate data with a view to maximize the explained variance (Davis 2002). However, spatial autocorrelation and spatial cross-correlation present in the data are ignored, and noise in the data stemming from spatial autocorrelation is also not captured. The method of minimum/maximum autocorrelation factors (MAFs) was first introduced by Switzer and Green (1984) as an approach to separate noise and signal in remote sensing data. MAF makes use of global spatial statistics, most notably the experimental covariance matrix and an experimental semivariogram matrix to characterize the short-scale variability of the data. Just as principal components, the MAF factors are linear combinations of the original variables. The first MAF contains maximum autocorrelation between neighboring observations. A higher-order MAF contains maximum autocorrelation subject to the constraint that it is orthogonal to lower-order MAFs and so the factors form a family of factors of decreasing autocorrelation. MAF analysis thus provides a more satisfactory method of orthogonalizing spatial data than PCA. The method has application whenever dimension reduction becomes an issue in geospatial data, and retaining the spatial autocorrelation is desired. MAF has been seen to be more effective than PCA when combined with

classification techniques such as K-NN (Drummond et al. 2010) or linear discriminant analysis (Mueller and Grunsky 2016; Grunsky et al. 2017). For example, Grunsky et al. (2017) showed that it was possible to use the first six MAF factors of the geochemical composition of the Australian surface regolith, followed by LDA to map the underlying crustal architecture, despite secondary modifications due to transport and weathering effects. It should be noted that this represents reduction in the number of variables to 6 from a total of 50 geochemical variables compared to 8 in the case of PCA and 10 if raw variables were used.

Apart from dimension reduction, the most common use in the geosciences lies in the geostatistical estimation and simulation of multivariate data. The MAF method was first applied by Desbarats and Dimitrakopoulos (2000) to simulate pore size distributions. Since this application, MAF has become one of the standard tools for spatial decorrelation as a preprocessing step for geostatistical simulation. The incorporation of MAF was extended to block simulation by Boucher and Dimitrakopoulos (2012), further highlighting the usefulness of the approach for large-scale mining operations. MAF was also used for factorial kriging of geochemical data from Greenland (Nielsen et al. 2000). The authors noted that a combination of maps of MAFs 1, 2, and 3 in a color ternary image resulted in good discrimination of the major provinces of South Greenland highlighting the potential of MAF analysis to identify geochemical boundaries in a region.

There are two approaches which can be used to derive MAFs, data driven or model driven (Rondon 2012). The data-driven approach is based on the sample covariance matrix and a semivariogram matrix at a suitably chosen lag spacing; in contrast, the model-driven approach is based on a linear model of coregionalization (LMC) with two model structures, and the coefficient matrices of the model are used to derive the factors. The model-based approach has been investigated extensively to determine whether extensions to more than two model structures could be used to derive factors; however, an extension to more complex LMCs is not possible (Vargas-Guzman and Dimitrakopoulos 2003; Bandarian et al. 2008), which is a consequence of the non-commutativity of square matrices. One exception is the case when the LMC consists of multiple structures whose coefficient matrices are such that all but one form a commuting family in which case a model-based approach will lead to an LMC that is diagonal (Tran et al. 2006).

Calculation of MAFs

A typical workflow for the application of data-driven MAF is as follows:

1. Compute the variance-covariance matrix Σ_0 of the centered data and determine its principal component decomposition

$$\Sigma_0 = P\Lambda P^T$$

with the entries in Λ arranged in decreasing order, and the matrix P is the corresponding orthogonal matrix of eigenvectors.

2. Compute the PCA scores $\hat{\mathbf{z}}(\mathbf{u}_i) = \mathbf{z}(\mathbf{u}_i)P\Lambda^{-1/2} = \mathbf{z}(\mathbf{u}_i)\Sigma_0^{-1/2}$. At this stage, the new variables have variance 1.
3. Compute the semivariogram matrix $\hat{\Gamma}(\mathbf{h}_0) = \Lambda^{-1/2}P^T\Gamma(\mathbf{h}_0)P\Lambda^{-1/2}$ for $\hat{\mathbf{z}}$ at the chosen lag $\mathbf{h}_0$, and determine its spectral decomposition again ordering the eigenvalues in descending order: $\hat{\Gamma}(\mathbf{h}_0) = Q\Lambda_1Q^T$
4. Put $\mathbf{y}(\mathbf{u}_i) = \hat{\mathbf{z}}(\mathbf{u}_i)Q$. Thus the overall transformation is $\mathbf{y}(\mathbf{u}_i) = \mathbf{z}(\mathbf{u}_i)A$ with

$$A = P\Lambda^{-1/2}Q.$$

The matrix A diagonalizes Σ_0 and $\Gamma(\mathbf{h}_0)$ simultaneously by congruence:

$$A^T\Sigma_0A = Q^T\Lambda^{-1/2}P^T\Sigma_0P\Lambda^{-1/2}Q = I$$

and

$$A^T\Gamma(\mathbf{h}_0)A = Q^T\Lambda^{-1/2}P^T\Gamma(\mathbf{h}_0)P\Lambda^{-1/2}Q = Q^T\hat{\Gamma}(\mathbf{h}_0)Q = \Lambda_1.$$

In the model-driven approach, the variables are first standardized or converted to normal scores. Experimental direct and cross semivariograms are computed based on a suitably chosen lag spacing as represented by the vector $\mathbf{h}_0$. This step is followed by fitting an LMC composed of two structures to the experimental semivariograms:

$$\Gamma(h) = B_1g_1(h) + B_2g_2(h)$$

Here g_1 and g_2 are allowed covariance model functions, and B_1 and B_2 are positive semi-definite coefficient matrices. Their sum is assumed to represent the covariance matrix of the data. It is further assumed that the range of the first covariance model function is less than that of the second; in many cases, the first model is the nugget covariance. The sum of the matrices $B = B_1 + B_2$ is treated as the variance-covariance matrix of the data, and the MAF transformation is determined from B and B_1 using steps 1 and 3 from the procedure above. The construction of the MAF transformation can also be seen as the solution of the generalized eigenvalue problem (Bandarian and Mueller 2008).

Irrespective as to whether the data-driven or model-driven approach is adopted, the factors are ordered in decreasing continuity in contrast to PCA, where spatial behavior is ignored.

The matrix $\mathbf{Q}$ derived in step 3 can be interpreted as containing the correlations between the PCA factors derived in step 1 and the MAF factors (Rondon 2012). The matrix $\mathbf{Q}$ is an orthogonal matrix and thus a composition of rotations and reflections; as a consequence, PCA and MAF factors are rarely equivalent, and the proportion of variance of the original data explained via MAF differs from that explained via the factors or the PCA.

It can also be shown that the MAF factors and the raw data are related by

$$\begin{aligned} E\left(Y(u)^T Z(u)\right) &= E\left(A^T Z(u)^T Z(u)\right) = A^T \Sigma_0 \\ &= \mathbf{Q}^T \Lambda^{-1/2} \mathbf{P}^T \mathbf{P} \Lambda \mathbf{P}^T = \mathbf{Q}^T \Lambda^{1/2} \mathbf{P}^T = A^{-1}. \end{aligned}$$

Thus the inverse of A which is required for back-transformation in the case of simulation or estimation does not need to be computed through inversion, but simply through matrix multiplication (Rondon 2012). In the case when the data are normalized, the expectation $E(Y(u)^T Z(u))$ is nothing other but the correlation matrix between the MAF factors and the raw data, which is analogous to the interpretation in the case of PCA.

A guided application is provided in Rondon (2012) where the normal scores of cadmium (Cd), cobalt (Co), chromium (Cr), and nickel (Ni) metal concentrations (ppm) from the Jura data set (Atteia et al. 1994) are spatially decorrelated with the data-driven and model-driven approaches. The author provides a detailed comparison of the outputs from a simulation study which shows that overall there is little difference in the performance of the two approaches.

Since the data-driven approach does not make any assumptions about the model of continuity, and so is much less restrictive than the model-driven approach, it is the preferred method in geostatistical studies as well as exploratory work.

MAF Biplots

As is the case for PCA, we may use the MAF scores and loadings to construct form biplots based on selected MAF factors. The scores are given by $Y(u) = Z(u)A$, and the matrix A is the corresponding loading matrix. The columns of Y are the principal coordinates, represented as dots, and the rows of the inverse loadings matrix are the analogues of the standard coordinates (represented as arrows).

MAF Analysis for Geochemical Surveys

The analysis of geochemical survey data is one specific area of application for MAF. The motivation is that typically many variables need to be analyzed jointly and for process discovery or hypothesis building, exploratory multivariate statistical methods are applied including PCA. However, the application of a PCA ignores any spatial dependence among variables which might make MAF more appropriate. When analyzing geochemical survey data, attention needs to be paid to the compositional nature of these, and this in turn requires pre-processing of the data through an appropriate log-ratio transformation, such as an additive (alr), a centered (clr), or an isometric (ilr) log-ratio transformation.

The most common choice is to use the clr-transformation. In this case, the covariance matrix Σ_{clr} of the transformed data is singular, and the PCA of Σ_{clr} can be written as $\Sigma_{clr} = [U_H, D^{-1/2} \mathbf{1}_D] \Lambda [U_H, D^{-1/2} \mathbf{1}_D]^T$, where D denotes the number of clr-variables. The matrix $U = [U_H, D^{-1/2} \mathbf{1}_D]$ is orthogonal and contains the eigenvectors of Σ_{clr} . The matrix $\Lambda = \text{diag}(-\lambda_1, \dots, \lambda_{D-1}, 0)$ is the diagonal matrix of eigenvalues arranged in descending order, with the last eigenvalue equal to 0 corresponding to the eigenvector $\mathbf{u}_D = D^{-1/2} \mathbf{1}_D$ and H is subspace orthogonal to $\mathbf{u}_D$. To complete the MAF transformation, the second decomposition is based on a suitably chosen semivariogram matrix chosen from the set $\{\Gamma_H(h_\ell) = U_H^T \Gamma_{clr}(h_\ell) U_H, \ell = 1, \dots, L\}$ of positive definite $(D-1) \times (D-1)$ matrices (Mueller et al. 2020).

Application

The Tellus geochemical survey was conducted between 2004 and 2007 and covers the region of Northern Ireland, UK (GSNI 2007; Young and Donald 2013). It consists of 6862 rural soil samples (X-ray fluorescence (XRF) analyses), collected at 20-cm depth, with average spatial coverage of 1 sample site every 2 km². Each soil sample site was assigned one of six broadly defined lithological classes (acid volcanics, felsic magmatics, basic volcanics, mafic magmatics, carbonatic, silicic clastics) as described in Tolosana-Delgado and McKinley (2016) and Mueller et al. (2020). A map of the sample locations colored by lithology is shown in Fig. 1.

Nine of the 50 geochemical variables available were chosen for analysis. They represent the bulk of the variability and make up the subcomposition Al, Fe, K, Mg, Mn, Na, P, Si, and Ti. The subcomposition was closed through the addition of a rest variable, and experimental direct and cross variograms of the clr data were computed for 30 lags at a nominal spacing of 1 km. The MAF transform was based on an estimate of the

Minimum Maximum Autocorrelation Factors,
Fig. 1 Map of Northern Ireland covered by broad lithological classes

Minimum Maximum Autocorrelation Factors, Fig. 2 Experimental semivariograms of the direct MAF semivariograms

Minimum Maximum Autocorrelation Factors, Fig. 3 Biplots of the first three MAFs; scores are color coded using the classification in Fig. 1

covariance matrix Σ_{clr} and the semivariogram matrix for the first lag $\Gamma_H(h_1)$. The direct variograms (Fig. 2) of the resulting nine factors show clear destructure with increasing factor index, with an increase in the nugget-to-sill ratio from about 0.1 for the first to 0.95 for the ninth factor and a decrease in range from 90 km to 15 km. Already for the fifth factor, the contribution of the nugget is at about 60% for the overall variability.

Biplot for MAF show a ternary system of mafics, felsics, and siliciclastic material (Fig. 3). The biplots of the first and second and first and third MAFs show a separation of

Minimum Maximum Autocorrelation Factors, Fig. 4 Scree plot for factorization based on MAF and cumulative variance explained

lithologies, which is no longer the case for the biplot of second and third MAF. The MAF biplot 1–2 indicates collinearity of Mn, Fe, and Ca, which is also still apparent in the MAF1–3 biplot; in contrast, there is no evidence of separation in the biplot contrasting MAF2 and MAF3.

The scree plot in Fig. 4 shows that the first factor explains approximately 36% of total variability, but in contrast to a PCA scree plot, the function showing the eigenvalues as a function of the MAF-index is not a decreasing function of the index. When compared with the standard PCA, the MAF clearly prioritizes spatial continuity (see Mueller et al. 2020).

The spatial maps of the MAF factors (Fig. 5) identify the lithologies reasonably well. The scores of the first two factors (MAF1 and MAF2) can be interpreted as presenting a broad balance between mafic elements and felsic elements. This feature is related to the contrast of the Paleocene Antrim basalts in the north west with the older rocks across the remainder of Northern Ireland. The intrusive igneous granite and granodiorite are also highlighted (MAF1, MAF2, and MAF3). Carbonates and clastics of different ages are differentiated by the fourth and fifth scores (MAF4 and MAF5). The scores of the sixth, seventh, and eight factors are less clear. The maps also highlight the decrease in spatial continuity of the factors within particular MAFs 1 and 2 having broader spatial features than the remaining MAFs.

Minimum Maximum Autocorrelation Factors, Fig. 5 Maps of MAF factors; top, 1 to 3; center, 4 to 6; bottom, 7–9 showing the decrease in spatial continuity; blue and yellow colors indicate low and high values, respectively

Summary

Decomposition of multivariate spatial data via MAF provides a powerful means to analyze spatial features of data and to characterize spatial scale. The resulting factors allow for univariate instead of multivariate geostatistical simulation and so provide more freedom in the choice of spatial covariance models than what is readily available in the multivariate case.

Mining Modeling

Youhei Kawamura

Division of Sustainable Resources Engineering, Hokkaido University, Sapporo, Hokkaido, Japan

Definition

A “digital twin” is defined as a virtual representation that serves as the real-time digital counterpart of a physical object or process. Digital twin technology is the result of continuous improvements in product design and engineering. Product drawings and engineering specifications have progressed from handmade drafting to computer-aided design and then to model-based systems engineering. On the other hand, the mining modeling is a relatively universal method of mathematical model construction and application intended to aid managerial personnel at various management levels in decision-making situations, which are frequently characterized by complicated relations of a quantitative as well as logical character.

The digital twin of a physical object is dependent on the digital thread – the lowest-level design and specification for a digital twin – for accuracy to be maintained. Changes to product design are implemented using engineering change orders (ECO). An ECO issued for a component item results in a new version of the item’s digital thread, and correspondingly, of the digital twin.

The concept of digital twins has started attracting attention due to the expansion of the Internet of Things (IoT) and the development of augmented reality (AR) and virtual reality (VR). However, a digital twin is different from general models and simulations. The concept of reproducing and

simulating an entity in a digital space using real-world data is not novel. However, the difference between a digital twin and general simulations is that changes in the real world can be reproduced in the digital space and are linked to each other in real time. With the expansion of IoT, real-world data is being automatically collected in real time and immediately reflected in digital spaces through networks. Thus, the similarity between real-world objects and digital-space models can be maintained. From this perspective, a digital twin is considered to be a “dynamic” virtual model in the real world. Digital twin technology for mining utilises can enable “mining modeling” for various purposes. Moreover, a digital twin for mining is a virtual representation of the physical world and is stored in a representative structure on a cloud data platform.

Introduction

The idea of “digital twin” is attracting considerable attention in the present-day mining industry and is expected to be used in various applications. Unlike older programmable logic controllers (PLCs), distributed control systems (DCSs), and mining execution systems (MESs), a digital twin leverages the latest updates in user interface (UI) and advanced visualization to allow operators recognitions in mine. The digital twin will be at the core of the interface in “smart mining,” which is rapidly gaining acceptance in the global mining industry. This industry is becoming increasingly serious regarding the environment, the economy, and safety.

Visualizing the development of the mine, environmental information, the position of workers, and the operational status of trucks at the central control room on the ground surface using communication systems is advantageous for mine operations. Rio Tinto has developed RTVis (Rio Tinto Visualization), a unique 3D visualization tool that can acquire geological information of open-pit mines, the progress of excavation and blasting, and the position information of trucks in real time (Rio Tinto 2020). RTVis superimposes information on a 3D model, determines the development status in real time in the central control room, and supports decision-making. This technology is an example of the use of digital twins for open-pit mining. These are the areas that “mining modeling” has been in charge of so far. The digital twin makes mining modeling easier to apply and is expected to evolve as a field. It is important to create a 3D model that serves as the “reflection destination,” providing an interface for sensing data of a mine whose shape keeps changing over time. CAD-based BIM/CIM in civil engineering and architecture cannot capture shape changes. Currently, two main methods are used for constructing a 3D model. One involves using a laser scanner, and the other is based on photogrammetry. With the rapid progress in drone technology in recent years, it has become possible to capture images and record

videos of large-scale objects, such as open-pit mines. Presently, photogrammetry-built 3D models are being used in open-pit mining projects (Obara et al. 2018).

Structure of Digital Twin

The structure of a digital twin is shown in Fig. 1. The “physical world” (mine site) is measured using a set of smart sensors, including a camera (image sensor), and the obtained data is transmitted through a wireless communication system, such as Wi-Fi or 5G, to a cloud server functioning as a data storage and sharing hub. The on-site analogue data is converted to digital data at the time of measurement by the sensors. A digital twin is created from the digital data on the cloud server. Any individual with access rights and sufficient network speed can utilize the created digital twin since it already exists in the cyber world (computational domain).

Comprehensive cloud data structures require a representative visualization layer for exploring the entire mining site. Thus, digital twins can be used to build mining sites virtually and obtain detailed information regarding mining processes, assets, and key settings (both current and recommended). In summary, by leveraging digital twins to collect and store data, spatial intelligence graphs can be created to model relationships and interactions between individuals, spaces, and devices at mining sites. In addition, a digital twin with advanced simulation capabilities allows for leveraging artificial intelligence and machine learning models from historical data, thereby simplifying future predictive testing. This methodology, unlike general simulations, allows for simulating extraction of information and optimisation of processing equipment in a virtual environment Fig. 1.

Mining Modeling, Fig. 1 Structure of digital twin

Modeling Technologies for Creating Digital Twin

Photogrammetry is the most effective technology for inexpensive and convenient 3D modeling of large-scale spaces. Photogrammetry uses structure from motion (SfM) and patch-based multi-view stereo (PMVS) as constituent technologies. In computer vision, methods for reconstructing an object in three dimensions on a computer based on images captured from various angles (multi-viewpoint images) have been studied extensively. SfM is the most versatile and accurate method, although several other reconstruction methods, such as using shadows in the image (shape from shading) and using focus (shape from defocus), are available.

Currently, a new and effective method is being developed to reconstruct 3D shapes using SfM to obtain models closer to the real object. This method is called multi-view stereo (MVS). When combined with patch-based technology, it is called “patch-based multi-view stereo.” As mentioned earlier, it is necessary to roughly divide modelling process into two steps to create a 3D model. Three-dimensional reconstruction using a multi-view image can yield information on the depth lost by projecting from a 3D image to a 2D image (Furukawa and Ponce 2010). A 3D model of the entire mine, similar to RTVis, is needed to visualize various types of information.

3D Model Reconstruction from Multi-view Images (Structure from Motion)

SfM is a method for simultaneously estimating the position and orientation of a camera and a sparse 3D shape (a collection of points, a sparse point cloud) from multiple images based on multi-view geometry. To estimate the position and orientation of the camera and the sparse point cloud from the multi-viewpoint image, mainly four steps are performed. In sequence, the feature points of the image are extracted and matched, the position and orientation of the camera are estimated, the 3D points are reconstructed via triangulation, and the camera orientation and the 3D point positions are optimized. These four steps are initially performed on two-viewpoint images as a pair. When the camera orientation and 3D points are reconstructed from the two-view images, one new image is added, and processing is performed again between the three images. When the posture estimation and restoration are completed, the images are added, and the process is repeated for all the multi-viewpoint images. Each process is explained below.

- Step 1: Extraction and Matching of Feature Points in Images.

To estimate the relative positions of the two cameras that have captured the two different viewpoint images, it is necessary to be able to first confirm multiple corresponding points between the images. Image feature

extraction technology (also called local image features) is used to search for corresponding feature points between two images. This technique considers a part of an image (a small set of pixels) composed of innumerable pixel values and determines characteristic points (key points) that indicate the overall tendency of that area. Algorithms such as scaled invariance feature transform (SIFT) can automatically calculate the feature points of images and associate them with each other (Lowe 2004). The image-to-image mappings that these algorithms automatically establish often contain errors. In other words, the feature points calculated between the two images are different, but they are related to each other. Random sample consensus (RANSAC) and epipolar constraints are used to eliminate such false correspondences (Isack and Boykov 2012). After performing RANSAC, only the feature points that satisfy the epipolar constraint (the corresponding points of the two images are located along a straight line) are recorded as the official corresponding points.

- Step 2: Estimation of Camera Position and Orientation.

When the search for the corresponding points of the two different viewpoint images is completed, the positions and orientations of the two cameras are estimated. At this stage, some correspondence is found between the two images. Therefore, the least-squares method is applied on these corresponding points to estimate the elementary matrix. Since the basic matrix contains the position and orientation of the cameras, these parameters can be estimated conveniently from more than two images.

- Step 3: Reconstruction of 3D Points via Triangulation.

Based on Steps 1 and 2, the corresponding points of the two images are searched, and the positions and orientations of the two cameras are estimated. The corresponding points satisfy an epipolar constraint as they lie on a straight line between the two images. Therefore, since one side and two angles are known, triangulation is possible, and the three-dimensional point position can be calculated. This calculation is repeated for each corresponding point to ascertain the position of the 3D point.

- Step 4: Optimization of Camera Orientation and 3D Point Position.

After Steps 1–3, the reconstruction of the 3D point is completed. The estimated camera position and orientation and the coordinates of the three-dimensional point overlap with each other as each process is performed. The deviation between the restored 3D point is projected onto the image plane, and the observation point on the corresponding image is called the reprojection error. This reprojection error is optimized, and the camera positions and orientation and the 3D points are estimated again Fig. 2.

Mining Modeling, Fig. 2 Flow of structure from motion (SfM)

Patch-Based Multi-View Stereo (PMVS)

MVS is a method of reconstructing the dense 3D shape of a subject using multi-view geometry under the condition that the position and orientation of the camera have already been clarified by SfM. MVS generates a dense point cloud from a sparse point cloud by estimating the pixel depth of a multi-viewpoint image. Specifically, the depth of each pixel is estimated by exploring the corresponding points in the paired images on the epipolar line using the camera orientation estimated by SfM. Thus, MVS searches for the corresponding points again separately from SfM. PMVS is an advanced method developed by Furukawa et al. to improve the accuracy of conventional MVS (Furukawa and Ponce 2010). PMVS estimates the normal vector and the depth of each pixel simultaneously. First, the feature points are detected, and the initial patch is calculated from the correspondence of the characteristic image area. Thereafter, the patch already obtained is extended to nearby pixels, and the process of removing erroneous corresponding points is repeated to generate a highly accurate and dense patch.

Surface Reconstruction from Point Cloud

The dense point cloud obtained after the processing using SfM and PMVS is automatically inferred from the color information, and the multi-viewpoint image of the object is obtained. After surface reconstruction, the 3D model is finally

completed. Figure 2 shows a series of steps from a multi-viewpoint image, summarizing the information in Sects. 4.1, 4.2, and 4.3. The lower-left model is the final model with an image pasted on the surface via surface reconstruction Fig. 3.

Examples of Cyber-Physical Implementation (Applications of Digital Twin for Mining)

This section presents specific examples of cyber-physical implementation in mining, including the multiple elemental technologies shown in Fig. 2. Cyber-physical implementation connects the physical world with the cyber world and improves work efficiency using the digital twin. The development of the digital twins for mining will enable rapid implementation of new technology at the mine site through actualization of the cyber-physical platform, which can appropriately allocate the work costs among the physical and cyber worlds. Specific usage examples are introduced separately for open-pit mines and underground mines.

Particle Size Distribution (PSD) Analysis and Blasting Optimization in Open-Pit Mine

The particle size distribution (PSD) of blasted rocks in hard rock mining has significant effects on the subsequent mine-to-mill process. For example, regions of fines and oversized

Mining Modeling, Fig. 3 Constructing 3D model from multi-view Images of mock piles

rocks substantially reduce the loading and hauling productivity. Given that the material transportation cost may reach 60% of the total operating costs, maintaining an appropriate rock fragment PSD is the ultimate objective of mine productivity optimization. Furthermore, the total milling process energy can be reduced by feeding rock fragments within the optimum particle size ranges. For nearly three decades, the mining industry has been reliant on conventional 2D photo-based rock fragmentation measurement methods, which analyze the PSD of rock fragments from 2D surface images of rock piles. Since the 1980s, various 2D photo-based rock fragmentation measurement systems have been introduced, such as IPACS, WipFrag, SPLIT, and PowerSieve. The drawbacks of conventional 2D photo-based rock fragmentation measurement (Con2D) methods have consistently been highlighted by researchers and practitioners. Therefore, fragmentation management is regarded as an essential task for mining engineers.

To overcome the limitations of Con2D, a 3D rock fragmentation measurement system (3DFM) based on photogrammetry technology has been proposed. 3DFM extracts the particle sizes from a 3D rock pile model, which facilitates accurate PSD measurement without scale objects and eliminates the need for excessive manual editing. Furthermore, a representative fragmentation of an entire blasting shot can easily be analyzed by generating a 3D model of an entire blasted rock pile (Jang et al. 2019).

In the field of computer vision, which involves equipping a computer with human-like visual function, multi-viewpoint images of an object captured from various angles are integrated to reconstruct the 3D shape of the object. Research on image-based modeling and rendering (IBMR) is being

actively conducted. The objective of our specific study is to develop a particle size distribution (PSD) estimation method that is both accurate and convenient, by applying IBMR to multi-view images of mock piles. In this system, a video or multiple photographs of the mock pile generated by blasting are captured by devices such as a drone or a smartphone. These multi-view images are uploaded to a cloud server via a network such as Wi-Fi or 5G. Then, information is passed from the physical world to the cyber world. A 3D model of the mock pile is generated from the multi-viewpoint images using the aforementioned photogrammetry technique. Thus, digital twins comprising polygons having the same scale as that of the real field are built in the cyber world. Subsequently, it becomes possible to automatically calculate the particle size of each fragmented rock using machine learning (e.g., through supervoxel processing) and to obtain an accurate particle size distribution curve. Since it is possible to create artificial intelligence (AI) with blasting design as the input and particle size distribution as the output, the subsequent blasting design can be optimized, and the new design can be adopted. Thereafter, the information is transferred to the physical world for use. The digital twin enables such blasting optimization Fig. 4.

Visualization of Ground Stress Concentration in Underground Mine

In future, underground mines are expected to become deeper. Therefore, the rock stress at the face will increase. To handle this situation, it is necessary to develop a solution that fully utilizes the latest technology. The main factor affecting underground work safety is rock stress. The purpose of this study was to improve the

Mining Modeling, Fig. 4 PSD analysis and blasting optimization

efficiency and safety of underground work by constructing a rock stress monitoring/visualization system based on a 3D model of an underground mine and AR technology.

We investigated the technology for visualizing the stress information of the rock mass in a tunnel using the natural feature-tracking method, which is a marker-less tracking method, and a point cloud 3D model of the underground tunnel. To construct the 3D model of an underground mine using photogrammetry, numerous images are required, and the shooting time becomes excessively long. To solve these problems, the methods of constructing a three-dimensional model of the mine using a 360° camera were compared with the method of using a conventional camera. From the experimental results, it was confirmed that reconstruction using a 360° camera is superior in terms of shadow time and effective restoration rate. An optimal method for building a 3D model in an underground mine has thus been developed.

With the point cloud model of the tunnel constructed using the proposed method, the visualization of rock stress by AR was examined. Initially, assuming that the rock stress distribution in the underground tunnel is divided into three regions, the point cloud model in the tunnel was edited in three colors. GPS connectivity is unavailable in underground tunnels, but

the amount of light is constant. Therefore, the natural feature-tracking method was adopted to match the real world with the point cloud model as a virtual object to confirm the extraction and collation of feature points between the images of the rock wall and to estimate the camera attitude and coordinates. From this information, the absolute coordinates of the point cloud model of the mine were determined. By associating these coordinates with the relative coordinates of the camera, the point cloud models of the corresponding colors were superimposed according to the wall surface projected on the camera. An AR system based on this point cloud model can be the basis for visualizing rock stress in real time after the underground monitoring system is completed. This can enable underground workers to identify changes in stress in real time. The system is ultimately expected to provide a safer and more productive work environment for underground workers Fig. 5.

Conclusion

The development of new technologies to improve efficiency and safety in mine development is accelerating. This is further

Mining Modeling, Fig. 5 AR visualisation system for rock stress in an underground mine

boosted by the inevitable fusion of mining with other disciplines. Among them, smart mining (Mining 4.0) represents a fusion of mining with information engineering, offering new possibilities in the mining industry. Furthermore, digital twins are becoming more important as the core technology for smart mining. A digital twin connects the physical and cyber worlds as an effective interface and contributes to the improvement of efficiency and safety by enabling visualization of mining operations.

Modal Analysis

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Modal analysis is the study of system components in the frequency domain. In the geosciences, it is especially important in igneous and sedimentary petrography. It assumes that minerals

are randomly distributed in the rocks being studied and that proportions of the rock-forming crystals (or other types of rock particles) can be determined by point counting using a special microscope or microprobe. For points forming a regular grid, the presence or absence of the rock-forming minerals is counted to measure the volume percentages of the minerals considered. If distances between points are sufficiently long, exceeding linear dimensions of the mineral grains considered, the binomial distribution and its normal approximation can be used to model these presence-absence data.

Introduction

In the geosciences, the technique of modal analysis was introduced by Chayes (1956) for widespread use in petrography; it had several precursors. Delesse (1848) introduced the principle of measuring volume percentage values of constituents of rocks by measuring the presence of every constituent at equally spaced points along lines. However, the initial method was exceedingly laborious as described by Johannsen (1917). Delesse's preferred method was to trace, on oiled paper, the outline of each constituent as shown on polished slabs. After coloring the resulting drawing, it was pasted on tinfoil and cut apart for each component, soaked off the paper, and weighed. Half a century later, Rosiwal (1898) introduced his improved method of linear measurements. Subsequently Shand (1916) described the method of employing a mechanical stage as part of the microscope that became generally used, because it requires very few measurements. Other early applications of modal analysis include Glagolev (1932) and Krumbein (1935).

Chayes (1956) brought mathematical statistics to bear on how to use the stage. His technique is based on the binomial distribution, which is a discrete probability distribution with parameters n (= number of points counted) and p (= number of points on mineral considered). It is assumed that n independent experiments are performed, each answering a yes-no question with probability p of obtaining a Boolean-value (0 or 1) outcome. The probability of no success satisfies $q = 1 - p$. A single success-failure experiment is also called a Bernoulli trial.

Binomial Distribution

The probability $P(k, n)$ of k successes in n experiments satisfies the binomial frequency distribution:

$$P(k, n) = \binom{n}{k} p^k q^{n-k} \text{ where } \binom{n}{k} = \frac{n!}{k!(n-k)!}$$

The mean μ of this distribution satisfies $\mu = np$, and the standard deviation is $\sigma = \sqrt{npq}$.

The following example illustrates the application of the binomial distribution in petrographic modal analysis. Suppose that 12% by volume of a rock consists of a given mineral "A." The method of point counting is applied to a thin section of this rock. Suppose that 100 points are counted. From $p = 0.12$ and $n = 100$, it follows that $q = 0.88$ and

$$\mu = np = 12; \sigma = \sqrt{npq} = \sqrt{12 \times 0.88} = 3.25.$$

If the experiment of counting 100 points would be repeated many times, the number of times (K) that the mineral "A" is counted would describe a binomial distribution with mean 12 and standard deviation 3.25. According to the so-called central-limit theorem, a binomial distribution approaches a normal distribution if n increases. Hence, we can say for a single experiment that:

$$P(\mu - 1.96\sigma < K \leq \mu + 1.96\sigma) = 0.95$$

or

$$P(5.6 < K \leq 18.4) = 95\%$$

The resulting value of K is between 5.6 and 18.4 with a probability of 95%.

This precision can be increased by counting more points. For example, if $n = 1000$, then $\mu = 120$ and $\sigma = 10.3$ and

$$P(99.8 < K \leq 140.2) = 95\%$$

This symmetrical probability can also be written as $k = 120 \pm 20.2$. To compare the experiment of counting 1000 points to that for 100 points, the result must be divided by 10, giving $k' = 12 \pm 2.02$. This number represents the estimate of volume percentage for the mineral "A." It is $3.25/(10.3/10) = 3.2$ times as precise as the first estimate for 100 points only. It is noted that this increase in precision agrees with the formula $\sigma^2(\bar{x}) = \sigma^2(x)/n$ for the population variance of $\bar{x}$ representing the mean of n values. The method of modal analysis has been discussed in more detail by Chayes (1956).

Antarctic Meteorite Case Study

Petrographic modal analysis is usually performed in conjunction with other methods such as chemical analysis of rock considered, as seen in McKay et al. (1999), that is taken here

as an example. This particular study describes a preliminary examination of the Antarctic Meteorite LEW 87051 (total weight 0.6 g) which is porphyritic in texture, with equant, euhedral to subhedral olivine phenocrysts ~0.5 mm wide set in a line-grained groundmass of euhedral plagioclase laths and interstitial pyroxene, Fe-rich olivine, kirschsteinite, and some minor constituents. Microprobe modal analysis was performed on these minerals by counting 721 points ranging from a maximum of 34.1% plagioclase to a minimum of 4.7% kirschsteinite, plus traces of several other minerals.

The information given in the preceding paragraph can be used to determine the approximate precision of the estimated volume percentage values by using the normal approximation of the binomial model as discussed in the preceding section. For very small frequencies, it would be better to approximate the binomial model by an asymmetric Poisson distribution model instead of by the normal distribution model. This is because, for very small frequencies, the binomial model approaches its Poisson distribution limit. According to Hald (1952), this limit can be set at $\theta < 0.1$, where $\theta = \mu/n$. This lower limit criterion is not met for kirschsteinite in the current example with $\theta = 0.047$ suggesting that use of the Poisson model would be better. Consulting tables published by Mantel (1962), and later reproduced by Johnson and Kotz (1969), then give its 95% confidence interval as $P(23.6 < K \leq 48.3) = 95\%$ instead of $P(22.6 < K \leq 45.3) = 95\%$ as results from the normal approximation of the binomial distribution. This is a very small improvement only.

Summary and Conclusions

The purpose of petrographic modal analysis is to determine the volume percentages of rock constituents from thin sections under the microscope. The spacing between points at which the constituents are counted should be sufficiently wide to avoid counting the same grain more than once. Precision of the results can be determined by using the binomial distribution model. For rare constituents, the Poisson model can be used. The Antarctic Meteorite LEW 87051 (total weight 0.6 g) was taken for example.

Moments

Jessica Silva Lomba¹ and Maria Isabel Fraga Alves²

¹CEAUL, Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal

²CEAUL & DEIO, Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal

Definition

Statistical moments can be introduced as features of (the probability distribution of) a random variable (RV). These numerical characteristics describe the behavior of the RV's distribution, such as location and dispersion, playing an important role in its identification, fitting, and estimation of parameters. Theoretical (population) moments are generally defined as expectations of functions of the RV, while their empirical counterparts, the sample moments, are basically computed as averages of similar functions of observations. The most common statistical moments in Geosciences are the following: the conventional first moment – *mean*, the second central moment – *variance*, and the standardized third and fourth central moments – *skewness* and *kurtosis*. However, Probability Weighted Moments (PWM) and L-moments have also been gaining visibility in this field.

Introduction

The term *statistical moment* refers to application of the mathematical concept *moment* as a tool in the study of probability, or frequency, distributions. First introduced by Karl Pearson (1893) in a short study of asymmetrical frequency curves, moments became widely spread probabilistic features across

all data-based pursuits. The choice of name *moment* connects strongly to the physical interpretation of the moments of mass distributions in Mechanics.

Broadly speaking, for a continuous real function of real variable $f(x)$ and $c, k \in \mathbb{R}$, consider the moment integral

$$\int_{-\infty}^{+\infty} (x - c)^k f(x) dx. \quad (1)$$

This is specially interesting when $k \in \mathbb{N}_0$, as (1) then defines the k^{th} moment of f about c . We restrict our exposition to the continuous case, for practical relevance, but discrete analogues can be found in the literature (e.g., Rohatgi and Saleh 2015). This concept is also extendable to higher dimensions (e.g., see “Multivariate Analysis of Variance”), though our main focus will be the univariate setting.

Illustrating the physical interpretation, consider the geophysical study of the Earth’s gravity field by Jekeli (2011), exploring the relationship between low-degree spherical harmonics of the Earth’s gravitational potential and the moments of its mass density (Eq. 50 therein). It is seen that the 0th order density moment is proportional to the Earth’s *total mass*, the first moments are proportional to its *center of mass*, and the second moments define the *inertia tensor* – which can indicate asymmetry in mass distribution. We borrow these ideas for interpretation of statistical moments.

Throughout, we think of an RV X with continuous, univariate distribution and density functions F and $F' := f$ (see “Probability Density Function” – PDF). Moment systems allow identification and description of the distribution of X in terms of location (analogous to center of mass) and shape (including dispersion and symmetry about the center), as functions of its parameters. Historically, moments have been recommended in the context of Geosciences since the 1900s.

Since Pearson’s seminal work, generalizations of the conventional moments (or simply Moments) have been suggested, addressing shortcomings of the primary system. However, the conventional remains the most widely known. We present three systems’ definitions and usage, illustrated with applications in Geosciences.

Conventional Moments

Traditionally, the k^{th} moment of X refers to the expectation of X^k

$$\mu'_k := \mathbb{E}[X^k] = \int_S x^k f(x) dx, \quad (2)$$

also known as *raw moment*, stemming from (1) with f the PDF of X , $c = 0$, and integrating over the variable’s support S . Notice $\mathbb{E}[X^k]$ in (2) exists only if $\mathbb{E}|X|^k := \int |x|^k f(x) dx < \infty$.

It becomes apparent that $\mu'_0 = 1$ gives the total probability ($\sim$ total mass). The *first moment* of X corresponds to the *mean* or *expected value* of the distribution, $\mu := \mathbb{E}[X]$, if it exists, and provides a measure of location, a central value of the distribution ($\sim$ center of mass).

Some distributions have all finite moments (e.g., see “Normal Distribution”), but not all moments of a distribution necessarily exist (e.g., Cauchy distribution); however, existence of the k^{th} moment implies existence of all moments of lower order $0 < n < k$. The *Moment Generator Function* (MGF) of X is defined as

$$M(s) := \mathbb{E}[e^{sX}], \quad (3)$$

provided the expectation on the right exists around the origin, and so the moments of X appear as successive derivatives of $M(s)$ at that point: $M'(0) = \mathbb{E}[X]$; $M''(0) = \mathbb{E}[X^2]$; in general, $M^{(k)}(0) = \mathbb{E}[X^k]$, for $k \geq 1$. The MGF may not exist, but existence of $M(s)$ implies existence of all order μ'_k , uniquely determining F .

If $\mathbb{E}[X] < \infty$, useful features arise by considering the moments centered about the mean, the *central moments*, of X

$$\mu_k := \mathbb{E}[(X - \mu)^k] = \int_S (x - \mu)^k f(x) dx, \quad (4)$$

as they directly inform on the distribution’s shape. These can be computed from raw moments, and *vice versa*. The first central moment is trivially 0, but, when they exist, higher order ones are specially relevant:

– Provided $\mathbb{E}|X|^2 < \infty$, then

$$\sigma^2 := \mu_2 = \mathbb{E}[X^2] - (\mathbb{E}[X])^2 \quad (5)$$

is the *variance* of X , and measures dispersion around the mean ($\sim$ moment of inertia); the square root, σ , is the *standard deviation*, expressed in the units of X , and its ratio by the mean results in the *coefficient of variation*

$$c = \frac{\sigma}{\mu}; \quad (6)$$

(see “Variance,” “Standard Deviation”);

- For symmetric distributions, all odd central moments are 0.
- The third and fourth *standardized* central moments give dimensionless measures of asymmetry and peakedness of distributions, respectively, the *coefficient of skewness*

$$\gamma_1 := \frac{\mu_3}{\sigma^3} \text{ and kurtosis } \gamma_2 = \frac{\mu_4}{\sigma^4}.$$

This topic is comprehensively addressed in Chapter 3 of Rohatgi and Saleh (2015).

The primary practical interest of these features is to compare them, in a way, to their empirical counterparts. For RV collection $X_1, X_2, \dots, X_n$, the k^{th} sample moment and sample central moment (cf. Rohatgi and Saleh 2015, Chapter 6) are defined, respectively, by

$$m'_k := \frac{1}{n} \sum_{i=1}^n X_i^k \quad \text{and} \quad m_k := \frac{1}{n} \sum_{i=1}^n (X_i - \bar{X})^k \quad (7)$$

where the common average $\bar{X} := m'_1$ denotes the *sample mean*. When $\{X_i\}_{i=1}^n$ constitute a random sample (RS) – independent, identically distributed (i.i.d) RVs – if μ'_k exists, the statistic m'_k is a consistent and unbiased estimator for that parameter. In fact, $\bar{X}$ is μ 's linear unbiased estimator of minimum variance (see “Best Linear Unbiased Estimator”). The sample central moments are generally not unbiased for their population analogues. Hence, the *sample variance* is commonly defined as

$$S^2 := \frac{n}{n-1} m_2, \quad (8)$$

an unbiased estimator for σ^2 (not so for $S = \sqrt{S^2}$). Regarding higher orders, the *sample coefficient of skewness* and *sample kurtosis*, respectively,

$$g = \frac{n^2}{(n-1)(n-2)} \frac{m_3}{S^3} \quad \text{and} \quad (9)$$

$$k = \frac{n^2}{(n-2)(n-3)} \left[\left(\frac{n+1}{n-1} \right) \frac{m_4}{S^4} - 3 \frac{(n-1)^2}{n^2} \right] + 3,$$

are possibly markedly biased estimators of γ_1 and γ_2 , with undesirable algebraic bounds determined by the sample size, $|g| \leq \sqrt{n}$ and $k \leq n+3$ (Hosking and Wallis 1997), and are highly outlier-sensitive. Mind that software usually computes the sample *excess kurtosis*, $k-3$, by comparison with the Normal distribution ($\gamma_2 = 3$).

Sampling distributions and asymptotic properties of these statistics have been widely studied and yield extremely useful results, like the Central Limit Theorem and Monte Carlo methods.

Other functions of moments relevant in applications can be listed, especially in the context of multivariate and spatial problems. Chapter 4 of Rohatgi and Saleh (2015) includes a

detailed exposition of generalizations of (2)–(4) to multiple RVs. We briefly mention a few aspects:

- The *covariance* between two RVs X and Y

$$\text{cov}(X, Y) := \mathbb{E}[(X - \mathbb{E}[X])(Y - \mathbb{E}[Y])] = \mathbb{E}[XY] - \mathbb{E}[X]\mathbb{E}[Y] \quad (10)$$

(if the expectations exist) provides a measure of joint variation, particularly, $\text{cov}(X, X) = \sigma_X^2$; this concept is generalized for n -dimensional vectors by the (symmetric) *variance-covariance* matrix, where the main diagonal shows individual variances and off-diagonal entries show pairwise covariances;

- While $\text{cov}(X, Y)$ points if Y tends to increase or decrease when X increases (respectively, $\text{cov}(X, Y) > 0$ or $\text{cov}(X, Y) < 0$), the *correlation coefficient*

$$\rho_{X,Y} = \text{corr}(X, Y) := \frac{\text{cov}(X, Y)}{\sigma_X \sigma_Y} \quad (11)$$

indicates the relationship's strength. Note $|\rho_{X,Y}| \leq 1$, the equality equivalent to linear association between X and Y (see “Correlation Coefficient,” “Multiple Correlation Coefficient”).

- If X and Y are independent, $\text{cov}(X, Y) = 0 = \rho_{X,Y}$, i.e., X and Y are uncorrelated; the converse is not necessarily true;
- For a bivariate sample $\{(X_i, Y_i)\}_{i=1}^n$, these characteristics are estimated by the *sample covariance* and *correlation coefficient*, respectively,

$$S_{X,Y} := \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y}) \quad \text{and} \quad (12)$$

$$R_{X,Y} := \frac{S_{X,Y}}{S_X S_Y};$$

- In Geostatistics, for a stochastic process $Z(s)$, a common generalization is the *variogram*

$$2\gamma(s_1, s_2) := \mathbb{E}[(Z(s_1) - \mathbb{E}[Z(s_1)]) - (Z(s_2) - \mathbb{E}[Z(s_2)])]^2, \quad (13)$$

representing the variance of the difference of the process at distinct points s_1, s_2 . If $Z(s)$ is stationary, the variogram is simply the function of the distance $h = s_2 - s_1$, since $\gamma(s_1, s_2) = \gamma(0, s_2 - s_1) := \gamma(h)$. Assuming intrinsic stationarity

of $Z(s)$, for points $\{s_i\}_{i=1}^n$, the prevailing *empirical/experimental (semi)variogram* is computed as

$$2\hat{\gamma}(h) := \frac{1}{n(h)} \sum_{i=1}^{n(h)} (Z(s_i) - Z(s_i + h))^2, \quad (14)$$

with $n(h)$ the number of pairs of points at distance h , and several theoretical models are available to fit this estimate (see “Variogram,” “Stochastic Process,” and “Stationarity”).

Method of Moments

“Method of Moments”(MM) is a broad category including various estimation methodologies, applied in several contexts, presented in different ways, but built on the same basis: essentially, equating sample moments to their population match – a substitution principle.

We focus on estimation of parameters of an assumed distribution F from a RS $X_1, \dots, X_n$, although the principle can be generally applied to statistical models. Let $\theta = (\theta_1, \dots, \theta_p) \in \Theta$ be the parameter vector of F . Knowing population μ'_k are functions of θ , the MM estimate $\hat{\theta}$ is the solution to an equation system of the type

$$\mu'_k(\theta) = m'_k \text{ for } k = 1, \dots, m \quad (15)$$

with $m \geq p$ the smallest integer guaranteeing a determined system. In general, the MM estimator of $\lambda = g(\mu'_1, \mu'_2, \dots, \mu'_k)$, a real-valued function of moments, is simply $\hat{\lambda} = g(m'_1, m'_2, \dots, m'_k)$; if g is continuous, $\hat{\lambda}$ is a consistent estimator for λ , asymptotically normal under mild conditions (Rohatgi and Saleh 2015, Chapter 8). Hence, some raw moment equations in (15) are frequently replaced by central moment relatives.

Compared to other methods (e.g., “Maximum Likelihood”), MM estimators are more straightforwardly computed, despite being usually less efficient and possibly resulting in inadmissible estimates $\hat{\theta} \notin \Theta$.

Applications in Geosciences

Moments and MM have been vastly applied in many fields of Geosciences. We mention a few examples:

- A frequent use of the variogram is *Kriging* – an optimized spatial interpolation method (see “Kriging”), prolific in Geostatistics’ literature since the 1960s.

- Building on the concept of *cumulant* – a combination of moments, generated by the logarithm of the MGF – Dimitrakopoulos et al. (2010) suggested a modeling (and, in subsequent work, simulation) approach for non-linear, non-Gaussian spatial data by introducing high-order *spatial cumulants*. These were found to efficiently capture complex spatial patterns and geological characteristics. The associated simulation methodology for spatially correlated attributes is shown to be advantageous compared to previous multiple-point (MP) approaches (see “Multiple Point Statistics”).
- Osterholt and Dimitrakopoulos (2018) addressed limitations of traditional variogram-based stochastic simulation techniques in capturing non-linear geological complexities of orebodies; the authors revisit MP simulation as an algorithm for the simulation of the geology for mineral deposits, an approach based on high-order spatial statistics and a type of extension of *kriging* systems. This method, which allows for resource uncertainty assessment, is applied to the Yandi channel iron ore deposit.
- Recently, Wu et al. (2020) studied how soil properties’ distribution characteristics influence probabilistic behavior of shallow foundations’ total and differential settlements. Focusing on the influence of the first four moment statistics, used to define the PDF of elastic modulus E , on the settlement’s distribution, the authors suggest a moment-based simulation method for modeling E as a 2-dimensional non-Gaussian homogeneous field. The study (via Monte Carlo simulations) shows that mainly skewness of E significantly influences total/differential settlements and suggests greater attention be given to identifying low-skewed situations, which may result in dangerous unexpectedly large settlements.

Probability Weighted Moments

The PWM comprise another valuable system to characterize probability distributions, whose theory parallels that of conventional moments. Introduced by Greenwood et al. (1979), the primary aim was deriving expressions for parameters of continuous distributions with explicit inverse function $\chi(\cdot)$ – the *quantile function*, satisfying $\chi(F(x)) = x$, $x \in S$. PWM have been extensively used in Geosciences, counteracting some conventional moments’ drawbacks leading to unsatisfactory inference. See Hosking and Wallis (1997) and references therein for further details.

The PWM of X are defined as

$$\begin{aligned} M_{p,r,s} &:= \mathbb{E}[X^p F(X)]^r (1 - F(X))^s \\ &= \int_S x^p (F(x))^r (1 - F(x))^s f(x) dx, \text{ with } p, r, s \in \mathbb{R}, \end{aligned} \quad (16)$$

where similarities with (2) are clear: $\mu'_k = M_{k,0,0}$, $k \in \mathbb{N}_0$. Their usefulness stems from being translated in terms of $\chi(u)$, $0 < u < 1$: contrast the notable PWM

$$\alpha_s := M_{1,0,s} = \int_0^1 \chi(u) (1 - u)^s du, s \in \mathbb{N}_0 \quad (17)$$

$$\beta_r := M_{1,r,0} = \int_0^1 \chi(u) u^r du, r \in \mathbb{N}_0 \quad (18)$$

against the redefined (2)

$$\mu'_k = \int_0^1 (\chi(u))^k du, k \in \mathbb{N}_0. \quad (19)$$

Higher complexity of μ'_k is evident, as successively higher powers of $\chi(\cdot)$ are employed, absent from α_s and β_r .

Appealing properties of PWM include the following:

- $M_{p,r,s}$ exists for all $r, s \geq 0$ if and only if $\mathbb{E}|X|^p < \infty$.
- Complete determination and characterization of F by the sets $\{\alpha_s\}_{s \in \mathbb{N}_0}$ or $\{\beta_r\}_{r \in \mathbb{N}_0}$ if $\mathbb{E}|X| < \infty$ (note the two moments are functions of each other); however, interpretation as distribution's features is not apparent.
- Connection to expectations of *order statistics* $X_{1:n} \leq X_{2:n} \leq \dots \leq X_{n:n}$; particularly, $n\alpha_{n-1} = \mathbb{E}[X_{1:n}]$ and $n\beta_{n-1} = \mathbb{E}[X_{n:n}]$.
- Straightforward estimation – for i.i.d. $\{X_i\}_{i=1}^n$, the *sample PWM*

$$a_s := \frac{1}{n} \sum_{i=1}^n \binom{n-i}{s} X_{i:n} \binom{n-1}{s}^{-1}, s = 0, 1, \dots, n-1 \quad (20)$$

$$b_r := \frac{1}{n} \sum_{i=r+1}^n \binom{i-1}{r} X_{i:n} \binom{n-1}{r}^{-1}, r = 0, 1, \dots, n-1 \quad (21)$$

are unbiased estimators of α_s and β_r , also asymptotically normal if μ'_2 of F exists.

Applications: PWM Methods

The “PWM method” falls in the MM category, following the same principle as presented above: matching population $M_{p,r,s}$, expressed in terms of the parameters $\theta = (\theta_1, \dots, \theta_p)$ of F , with their empirical functionals, for example,

$$\alpha_s(\theta) = a_s, \text{ for } s = 0, 1, \dots, m \geq p. \quad (22)$$

These equations are, again, interchangeable with other convenient equalities of (functions of) PWM.

PWM-type estimators have been shown to be more robust to *outliers*, less subject to sampling variability and estimation bias, and frequently more efficient than conventional moment estimators, potentially even more accurate than Maximum Likelihood estimators for some smaller samples.

Generalized PWM (GPWM) methods have been suggested. We mention the GPWM estimators proposed by Diebolt et al. (2008) for the Generalized Extreme Value distribution (GEVd), employed in analysing annual daily precipitation maxima (see “Extrema”), as prescribed by *Extreme Value (EV) Statistics* framework.

PWM-GEVd estimates are valid under the shape parameter condition $\gamma < 1$ (equivalently, $\mathbb{E}|X| < \infty$); the goal was to extend the method's validity. The GPWM $\nu_\omega := \mathbb{E}[X\omega(F(X))]$, with convenient auxiliary functions $\omega(\cdot)$, written in terms of the GEVd's F three parameters $(\theta_1, \theta_2, \gamma)$. The GPWM estimators are $\hat{\nu}_{\omega_{ab}} := \int_0^1 \mathbb{F}_n^{-1}(u) \omega_{ab}(u) du$, with $\mathbb{F}_n^{-1}$, the empirical quantile function.

Solving the moment-equations system $\nu_\omega(\theta_1, \theta_2, \gamma) = \hat{\nu}_{\omega_{ab}}$ for three suggested $\omega_{ab}(\cdot)$ functions results in the desired GPWM parameter estimators. These are asymptotically normal, have broader validity domain and improved performance over PWM, especially for large values of γ (common in hydrology and climatology), while conserving conceptual simplicity and easy implementation.

L-moments

Since 1986, when J.R.M. Hosking first introduced the *L-moments*, a myriad of papers has been published detailing and applying this system and its properties. The fundamental information, for the purpose of this exposition, is compiled in Hosking and Wallis (1997), where L-moments are a stepping-stone for several Regional Frequency Analysis (RFA) techniques.

Derived as *linear combinations* of PWM, *L-moments* inherit the appealing features mentioned above. Particularly, estimation-wise, robustness to measurement errors and sample variability, while accounting for ordering in weighting observations, suggests appropriateness of L-moments for

analysis of EVs, paramount to various fields (e.g., seismology).

Define the k^{th} *L-moment* of X as

$$\lambda_k := \int_0^1 \chi(u) \cdot \sum_{i=0}^{k-1} (p_{k,i}^* u^i) du, \quad (23)$$

where

$$p_{k,i}^* := (-1)^{k-i} \binom{k}{i} \binom{k+i}{i} = \frac{(-1)^{k-i} (k+i)!}{(i!)^2 (k-i)!}. \quad (24)$$

With respect to the PWM (17) and (18), redefine (23) as

$$\lambda_{k+1} := (-1)^k \sum_{i=0}^k p_{k,i}^* \alpha_i = \sum_{i=0}^k p_{k,i}^* \beta_i. \quad (25)$$

The complete L-moment set exists and uniquely determines F if $\mathbb{E}|X| < \infty$, which is not true for conventional moments.

L-moments resolved the PWM interpretability issue, as they meaningfully describe a distribution: explicitly, the first four L-moments are

$$\begin{aligned} \lambda_1 &= \alpha_0 &= \beta_0 \\ \lambda_2 &= \alpha_0 - 2\alpha_1 &= 2\beta_1 - \beta_0 \\ \lambda_3 &= \alpha_0 - 6\alpha_1 + 6\alpha_2 &= 6\beta_2 - 6\beta_1 + \beta_0 \\ \lambda_4 &= \alpha_0 - 12\alpha_1 + 30\alpha_2 - 20\alpha_3 &= 20\beta_3 - 30\beta_2 + 12\beta_1 - \beta_0 \end{aligned} \quad (26)$$

where $\lambda_1 \in \mathbb{R}$ and $\lambda_2 \geq 0$ are the *L-location* and *L-scale*; for dimensionless, scale-independent measures of shape, consider the *L-moment ratios*, $\tau_r = \lambda_r / \lambda_2$, $r = 3, 4, \dots$, with highlight to the *L-skewness* and *L-kurtosis*

$$\tau_3 = \frac{\lambda_3}{\lambda_2} \quad \text{and} \quad \tau_4 = \frac{\lambda_4}{\lambda_2}. \quad (27)$$

Moreover, the *L-CV* $\tau = \lambda_2 / \lambda_1$ is akin to c in (6).

L-moment ratios are easier to interpret, as they satisfy $|\tau_r| < 1$ for finite-mean distributions, and, again, all odd-order τ_r of symmetric distributions are zero; also τ_4 is bounded relatively to τ_3 by

$$\frac{1}{4} (5\tau_3^2 - 1) \leq \tau_4 < 1. \quad (28)$$

The *L-statistics* are simply computable from linear combinations of the order statistics. *Sample L-moment* counterparts of (26) result from imputing the estimators (20) or (21) into the linear combinations in (25):

$$\begin{aligned} \ell_1 &= a_0 &= b_0 \\ \ell_2 &= a_0 - 2a_1 &= 2b_1 - b_0 \\ \ell_3 &= a_0 - 6a_1 + 6a_2 &= 6b_2 - 6b_1 + b_0 \\ \ell_4 &= a_0 - 12a_1 + 30a_2 - 20a_3 &= 20b_3 - 30b_2 + 12b_1 - b_0 \end{aligned} \quad (29)$$

with corresponding *sample L-skewness* and *sample L-kurtosis*

$$t_3 = \frac{\ell_3}{\ell_2} \quad \text{and} \quad t_4 = \frac{\ell_4}{\ell_2}. \quad (30)$$

These natural estimators enjoy attractive properties:

- ℓ_k are unbiased and t_r are asymptotically unbiased estimators, both being asymptotically normal if μ'_2 of X exists.
- ℓ_k behave nicely under linear transformations of data.
- Contrary to g and k in (9), t_3 and t_4 are not algebraically bounded w.r.t. sample size.
- t_3 and t_4 are generally less biased than g and k .
- The joint distribution of (t_3, t_4) is near-normal, a useful feature for some RFA procedures.

Alternative, less frequent, *plotting-position estimators* of L-moments can be found in Hosking and Wallis (1997).

Again, it is possible to establish the “L-moment method” as a MM fitting approach. It follows the substitution principle introduced above, equating the first $m \geq p$ L-statistics to their population parallels. For brevity, we refer to the Appendices of Hosking and Wallis (1997), showing L-moment-derived expressions for common use distributions’ parameters, including the Lognormal (see “Lognormal Distribution”) and GEVd, relevant in several Geosciences areas.

Among the most significant contributions of L-moments is the identification of distributions given a reduced set of summary statistics. For this purpose, heavily featured in RFA, the *L-moment Ratio Diagram* (LMRD) was introduced. This visual tool presents the relationship between two L-moment ratios for specific distributions. Usually, L-skewness *versus* L-kurtosis is plotted, as shown in Fig. 1 for some families of interest; this is specially useful for skewed distributions, but higher order ratios could be chosen. A similar plot of conventional skewness *versus* kurtosis would be uninformative.

Notice that 2-parameter distribution families correspond to a point in the LMRD (e.g., Normal), 3-parameter ones draw a curve (e.g., GEVd), different points on the curve imply different shape parameter values, and families with more parameters appear as two-dimensional regions. Marking the estimates (t_3, t_4) from a given RS on the LMRD, and evaluating its distance to the several distribution-specific curves, may point to appropriateness of fitting one distribution over another; this has multiple practical applications, as we

Moments, Fig. 1 LMRD:

Shaded region – general bounds (28); key to distributions: E – Exponential; G – Gumbel; GEV – GEVd; GLO – Generalized Logistic; GP – Generalized Pareto; L – Logistic; LN – Lognormal; N – Normal; U – Uniform (cf. Hosking and Wallis 1997, Appendix A.12)

mention below. In practice, $0 \leq \tau_3 \leq 0.5$ and $0 \leq \tau_4 \leq 0.4$ define the commonly appropriate region of the LMRD.

Regional Frequency Analysis and Other Applications

The aim of the RFA approach suggested by Hosking and Wallis (1997), using an index-flow procedure, is to estimate quantiles of a frequency distribution (FD) at a given site by pooling data, or summary statistics, from sites judged to have similar FD. This is potentially problematic since FDs may not be exactly identical and magnitudes may be dependent across sites. Thus, steps are taken to guarantee accuracy and robustness of the analysis:

1. Screening the data – sites where data behave differently, needing closer inspection, are detected using a discordance measure built on L-moments.
2. Identifying and testing homogeneous regions – after grouping sites where the FDs are judged as approximately the same, L-moments are used in a heterogeneity measure to test if the region is acceptably close to homogeneous.
3. Choosing the FD – a goodness-of-fit L-moment-based measure, relating to the LMRD, is used to evaluate the fitting of candidate distributions to the data.
4. Estimating the FD – a regional L-moment algorithm is suggested for estimating regional and at-site quantiles.

L-moments clearly play a pivotal role at all stages of this process.

Additionally, we briefly mention recent papers with applications of L-moment methodologies to data of interest from Geosciences:

- Lee et al. (2021) have used the L-moment method to estimate the Gumbel distribution's parameters and related probabilities, while developing a new, EV theory-based approach of temporal probability assessment of future landslide occurrence from limited rainfall and landslide records.
- Silva Lomba and Fraga Alves (2020) developed an automatic procedure, based on the LMRD's Generalized Pareto-specific curve, for estimation of a crucial entity in EV Statistics, the threshold, showcased by accurate and efficient inference regarding significant wave height data.
- Papalexiou et al. (2020) evaluated the reliability of models' simulations for reproduction of historical global temperatures by comparing, based on L-moments and the LMRD (perceived as robust criteria), the distributional shape of historical/simulated temperatures, aggregated at different time scales.

Summary

As we have seen, common usefulness of moment-based methodologies includes data description, distribution identification, parameter estimation, dependence analysis, and further benefits could be mentioned (e.g., "Hypothesis Testing," "Autocorrelation"). We have explored advantages and drawbacks of three moment systems. The presented recent

applications to Geosciences show their appropriateness for diverse endeavors. Moreover, there is leeway for generalizations of the mentioned moments to be suggested (e.g., *Trimmed* L-moments). Moments are, in all, essential devices in Mathematical Geosciences.

Monte Carlo Method

Klaus Mosegaard

Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark

Definition

Any random process can, in principle, be represented by a computer program using pseudorandom numbers. If near-perfectly independent random numbers between 0 and 1 can be produced, appropriate functions of these numbers can simulate realizations of practically any probability distribution needed in technical and scientific applications. The development of Monte Carlo methods grew out of our ability to find those functions and algorithms.

The literature on Monte Carlo methods is vast, and the methods are many. We cannot cover everything here, but the intention is to provide a brief description of some of the most important techniques and their principles. After having reviewed basic techniques for random simulation, we shall move on to three high-level categories of Monte Carlo methods: testing, inference, and optimization. We shall also present some hybrid methods, as there is often no sharp borderline between the categories.

In the following, unless otherwise stated, we will consider continuous random variables over bounded (measurable) subsets of $\mathcal{R}^N$ and their probability densities, although many of the methods described are applicable more generally.

Methods

Basic Simulation Methods

Exact sampling of probability distributions is an important component of all Monte Carlo algorithms. Most important are the following methods (formulated for a 1 dimensional space):

Algorithm 1 The “Inverse Method” for a Continuous Random Variable with a Given, Everywhere Nonzero Probability Density

Let p be a probability density, and P its distribution function:

$$P(s) = \int_{-\infty}^s p(s)ds, \quad (1)$$

and let r be a random number chosen uniformly at random between 0 and 1. Then the random number x generated through the formula

$$x = P^{-1}(r) \quad (2)$$

has probability density p .

Algorithm 2 The Box-Muller Method for Gaussian Distributions

Let r_1 and r_2 be random numbers chosen uniformly at random between 0 and 1. Then the random numbers

$$x_1 = \sqrt{-2 \ln r_2} \cos(2\pi r_1) \quad (3)$$

$$x_2 = \sqrt{-2 \ln r_2} \sin(2\pi r_1) \quad (4)$$

are independent and Gaussian distributed with zero mean and unit variance.

As building blocks for some of the more sophisticated algorithms we shall discuss in the coming sections, we need to mention the following two algorithms for sampling in high-dimensional spaces:

Algorithm 3 Sequential Simulation

Consider a probability density p over an N -dimensional space decomposed into a product of N univariate conditional probability densities:

$$p(x_1, x_2, \dots, x_N) = p(x_1)p(x_2|x_1)p(x_3|x_2, x_1) \dots p(x_N|x_{N-1}, \dots, x_1). \quad (5)$$

Exact simulation of realizations from $p(x_1, x_2, \dots, x_N)$ can now be performed by first generating a realization $\hat{x}_1$ from $p(x_1)$, then a realization $\hat{x}_2$ from $p(x_2|\hat{x}_1)$, then a realization $\hat{x}_3$ from $p(x_3|\hat{x}_2, \hat{x}_1)$, and so on until we have a realization $\hat{x}_N$ from $p(x_N|\hat{x}_N, \dots, \hat{x}_1)$. The point $(\hat{x}_1, \dots, \hat{x}_N)$ is now a realization from $p(x_1, \dots, x_N)$.

The above type of algorithm is widely used for simulation of image realizations where the conditional probabilities are obtained from training images (see Strebel 2002).

The simplest way to sample a constant probability density is through a simple application of Algorithm (3) where all 1D conditional probability densities are constant functions. However, in the Markov Chain Monte Carlo algorithms we shall describe below, we need to perform uniform sampling via random walks whose design can be adapted to our sampling problem. This can be done in the following way:

Algorithm 4 Sampling a Constant Probability Density by a Random Walk

Given a uniform (constant) probability density, a sequence of random numbers $U_n (n = 1, 2, \dots)$ in $[0, 1]$, and a PROPOSAL DISTRIBUTION $q(\mathbf{x}^{(n+1)}|\mathbf{x}^{(n)})$ defining the probability that the random walk goes to $\mathbf{x}^{(n+1)}$, given that it starts in $\mathbf{x}^{(n)}$ (possibly with $q(\mathbf{x}^{(n+1)}|\mathbf{x}^{(n)}) \neq q(\mathbf{x}^{(n)}|\mathbf{x}^{(n+1)})$), then the points visited by the iterative random function V :

$$V(\mathbf{x}^{(n)}) = \begin{cases} \mathbf{x}^{(n+1)} & \text{if } U \leq \min \left[1, \frac{q(\mathbf{x}^{(n)}|\mathbf{x}^{(n+1)})}{q(\mathbf{x}^{(n+1)}|\mathbf{x}^{(n)})} \right] \\ \mathbf{x}^{(n)} & \text{otherwise} \end{cases} \quad (6)$$

asymptotically converge to a sample of the uniform distribution as n goes to infinity.

The above algorithms (1)–(4) are easily demonstrated and straightforward to use in practice. Algorithms (1) and (2) can without difficulty be generalized to higher dimensions.

Monte Carlo Testing

If we are interested in testing the validity of a parametric statistical model of, say, an inhomogeneous earth structure, we can select an appropriate function (a “statistic”) summarizing important properties of the structure, for instance, a variogram. We can now generate Monte Carlo realizations of the structure and compute values of the statistic for each realization. By comparing the distribution of the statistics with the observed (or theoretical) value of the statistics, we can decide if our choice of model is acceptable (Mrkvicka et al. 2016). The decision relies on a statistical test measuring to what extent the observed statistics coincides with high probabilities in the histogram of simulated values.

The above testing approach can be seen as a tool to determine acceptable models satisfying given observations. This is related, but in principle more general, than the Monte Carlo inference methods described in the following. In these methods, the statistical model is fixed beforehand.

Monte Carlo Inference

Inference problems are problems where we seek parameters of a given, underlying stochastic model, designed to explain observable data $\mathbf{d}$. In physical sciences, technology, and economics, inference problems are often *inverse problems* which, in a probabilistic formulation, result in the definition of a *posterior* probability distribution $p(\mathbf{x}|\mathbf{d})$ describing our state of information about model parameters $\mathbf{x}$ after inference. Integrals of p over the parameter space can then provide estimates of event probabilities, expectations, covariances, etc. Such integrals are of the form

$$I = \int_{\chi} h(\mathbf{x})p(\mathbf{x})d\mathbf{x}, \quad (7)$$

where $p(\mathbf{x})$ is the posterior probability density. They can be evaluated numerically by generating a large number of random, independent realizations $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}$ from $p(\mathbf{x})$. The sum

$$I \approx \frac{1}{N} \sum_{n=1}^N h(\mathbf{x}^{(n)}). \quad (8)$$

is then an estimate of the integral. The fact that the integral (7) in high-dimensional spaces is more efficiently calculated by Monte Carlo algorithms than by any other method means that Monte Carlo integration has become important in numerical analysis.

For many practical inference problems, the model space is so vast, and evaluation of the probability density $p(\mathbf{x})$ is so computer intensive, that full information about $p(\mathbf{x})$ remains unavailable. In this case, we need algorithms that can do with values of $p(\mathbf{x})$ from one point at a time. The simplest of these algorithms is the rejection algorithm (von Neumann 1951):

The Rejection Algorithm

Algorithm 5 The Rejection Algorithm

Assume that $p(\mathbf{x})$ is a probability density with an upper bound $M \geq \max(p(\mathbf{x}))$. In the n th step of the algorithm, choose with uniform probability a random candidate point $\mathbf{x}_c$. Accept $\mathbf{x}_c$ only with probability

$$p_{\text{accept}} = \frac{p(\mathbf{x}_c)}{M}. \quad (9)$$

The set of thus accepted candidate points is a sample from the probability distribution $p(\mathbf{x})$.

The rejection algorithm is ideal in the sense that it generates independent realizations from bounded probability densities, but for distributions in high-dimensional spaces with vast areas of negligible probability, the number of accepted points is small. This makes the algorithm very inefficient, and for this reason random-walk-based algorithms were developed. The original version of this was the Metropolis Algorithm (Metropolis et al. 1953), but it was later improved by Hastings (1970):

Markov-Chain Monte Carlo (MCMC)

Algorithm 6 (Metropolis-Hastings).

Given a (possibly un-normalized) probability density $p(\mathbf{x}) > 0$, a sequence of random numbers $U_n (n = 1, 2, \dots)$ in $[0,1]$, and an iterative random function $V(\mathbf{x})$ sampling a constant probability density using Algorithm (4):

$$\mathbf{x}^{(n+1)} = V(\mathbf{x}^{(n)}). \quad (10)$$

Then the distribution of samples produced by the iterative random function W :

$$\begin{aligned} \mathbf{x}^{(n+1)} &= W(\mathbf{x}^{(n)}) \\ &= \begin{cases} V(\mathbf{x}^{(n)}) & \text{if } U_n \leq \min \left[1, \frac{p(V(\mathbf{x}^{(n)}))}{p(\mathbf{x}^{(n)})} \right], \\ \mathbf{x}^{(n)} & \text{otherwise} \end{cases} \end{aligned} \quad (11)$$

will asymptotically converge to $p(\mathbf{x})$ as n goes to infinity.

An extended form of this algorithm is obtained if $V(\mathbf{x})$ is sampling an arbitrary probability density $r(\mathbf{x})$, in which case the algorithm will sample the product distribution $p(\mathbf{x})r(\mathbf{x})$. This was suggested by Mosegaard and Tarantola (1995) as a way of sampling the posterior distribution in Bayesian/probabilistic inverse problems, where $r(\mathbf{x})$ is the prior probability density and $p(\mathbf{x})$ is the likelihood. In this way, a closed-form expression for the prior was unnecessary, allowing V to be available only as a computer algorithm.

It is important to realize that the design of the proposal algorithm (4) is critical for the performance of the Metropolis-Hastings algorithm. The proposal distribution $q(\mathbf{x}^{(n+1)}|\mathbf{x}^{(n)})$ will work efficiently only if it locally resembles the sampling distribution $p(\mathbf{x})$ (except for a constant). In this way, the number of rejected moves will be minimized.

In practice, any sampling with the Metropolis-Hastings algorithm needs to run for some time to reach equilibrium

sampling with statistically stationary output. The time (number of iterations) needed to reach this equilibrium is called the *burn-in time*, and it is usually found by experimentation. Another problem is that the algorithm is based on a random walk, and hence, sample points will not be independent when sampled closely in time. To determine the time spacing between approximately independent samples, a correlation analysis may be needed. Ways of avoiding poor sampling results were discussed by Hastings (1970).

Geman and Geman (1984) introduced the *Gibbs Sampler*, another variant of the Metropolis algorithm where sample points were picked along coordinate axes in the parameter space according to the conditional distribution $p(x_j|x_1, \dots, x_{j-1}, x_{j+1}, \dots, x_N)$, x_j being the parameter to be perturbed. Although this strategy gives acceptance probabilities equal to 1, it may not be practical when calculation of the conditional probability is computationally expensive.

Monte Carlo Inference for Sparse Models

The Metropolis-Hastings algorithm (6) can be formulated to allow variable dimension of the parameter vector $\mathbf{x}$ (Green 1995). This version of the algorithm is used in Bayesian inference when the number of parameters N is treated as an unknown (Sambridge et al. 2006), making it possible to work with sparse models, and thereby reducing the computational burden:

Algorithm 7 Reversible-Jump Monte Carlo

Let $p(\mathbf{x}, N)$ be a probability density over a subset of $\mathcal{R}^N$, augmented with its dimension parameter N . The Metropolis-Hastings algorithm (6) operating in the extended space with

$$V(\mathbf{x}^{(n)}, N^{(n)}) = \begin{cases} (\mathbf{x}^{(n+1)}, N^{(n+1)}) & \text{if } U_n \leq \min \left[1, \frac{q(\mathbf{x}^{(n)}, N^{(n)} | \mathbf{x}^{(n+1)}, N^{(n+1)})}{q(\mathbf{x}^{(n+1)}, N^{(n+1)} | \mathbf{x}^{(n)}, N^{(n)})} |J| \right], \\ (\mathbf{x}^{(n)}, N^{(n)}) & \text{otherwise} \end{cases} \quad (12)$$

where the proposal distributions $q(\mathbf{x}^{(q)} | \mathbf{x}^{(p)})$ and $q(\mathbf{x}^{(p)} | \mathbf{x}^{(q)})$ are expressed through the invertible, differential mappings:

$$\begin{aligned} \mathbf{x}^{(q)} &= h(\mathbf{x}^{(p)}, \mathbf{u}^{(p)}) \\ \mathbf{x}^{(p)} &= h'(\mathbf{x}^{(q)}, \mathbf{u}^{(q)}), \end{aligned} \quad (13)$$

$\mathbf{u}^{(p)}$ and $\mathbf{u}^{(q)}$ being random vectors with generally nonuniform distributions, and where $|J|$ is the Jacobian

$$|J| = \left| \frac{\partial(\mathbf{x}^{(p)}, \mathbf{u}^{(p)})}{\partial(\mathbf{x}^{(q)}, \mathbf{u}^{(q)})} \right|, \quad (14)$$

will sample the extended space according to $p(\mathbf{x}, N)$.

This algorithm will not only sample the space of models $\mathbf{x}$ (with varying dimension), but also the distribution N of the dimension itself.

Sequential Monte Carlo Methods

Estimating the evolution of a dynamic system is important in science and technology, for instance, in predicting the movement of an airplane in motion, or in numerical weather prediction. An important analytical tool in this field is the Kalman filter (Kalman 1960) which iteratively provides

deterministic, Bayesian, and linear updates to past predictions of system parameters. For large systems, however, the many parameters make the analytical handling of large covariance matrices computationally intractable. This led to the development of the ensemble Kalman filter (EnKF) (Evensen 1994, 2003) a Monte Carlo algorithm that avoids the covariance matrices and instead represents the Gaussian distributions of noise, prior and posterior by ensembles of realizations. A basic formulation is the following:

Algorithm 8 Ensemble Kalman Filter (EnKF)

Assume that data $\mathbf{d}$ at any time are related to the system parameters $\mathbf{x}$ through the linear equation $\mathbf{d} = \mathbf{H}\mathbf{x}$. If $\mathbf{X}$ is an $n \times N$ matrix of N realizations from the initial (prior) Gaussian distribution of system parameters, and if $\mathbf{D}$ is an $m \times N$ matrix with N copies of data $\mathbf{d} + \mathbf{e}_m$ where $\mathbf{d}$ is the noise-free data and each $\mathbf{e}_m$ is a realization of the Gaussian noise, it can be shown that if $\mathbf{K} = \mathbf{CH}^T(\mathbf{HCH}^T + \mathbf{R})^{-1}$, the columns of the matrix

$$\hat{\mathbf{X}} = \mathbf{X} + \mathbf{K}(\mathbf{D} - \mathbf{H}\mathbf{X}) \quad (15)$$

are realizations from the posterior probability density. Iterative application of these rules, where the posterior realizations in one time step are used as prior realizations in the next step, will approximately evolve the system in time according to the model equations and the uncertainties.

For more details about the implementation, see Evensen (2003).

A more recent, nonlinear, and non-Gaussian alternative to EnKF is the Particle Filter method (Reich and Cotter (2015), Nakamura and Potthast (2015) and van Leeuwen et al. (2015)). The standard particle filter is a bootstrapping technique (see below) operating in the following way:

Algorithm 9 Particle Filter

Assume that data $\mathbf{d}$ at any time are related to the system parameters $\mathbf{x}$ through the equation $\mathbf{d} = \mathbf{h}(\mathbf{x})$. After n time steps, let $\mathbf{x}_1^{(n)}, \mathbf{x}_2^{(n)}, \dots, \mathbf{x}_N^{(n)}$ be N initial realizations (“particles”) of the system parameters, representing the prior probability density

$$p(\mathbf{x}^{(n)}) = \sum_{i=1}^N \frac{1}{N} \delta(\mathbf{x}^{(n)} - \mathbf{x}_i^{(n)}). \quad (16)$$

Assume that the system is propagated forward in time by the generally nonlinear model f :

$$\mathbf{x}^{(n)} = f(\mathbf{x}^{(n-1)}) + \mathbf{e}^{(n)} \quad (17)$$

where $\mathbf{e}^{(n)}$ is modelization noise introduced in the n 'th time step. If the likelihood function for time step n is

$$p(\mathbf{d}^{(n)} | \mathbf{x}^{(n)}) = p_e(\mathbf{d} - \mathbf{h}(\mathbf{x}^{(n)})) \quad (18)$$

We can use Bayes' rule and obtain

$$\begin{aligned} p(\mathbf{x}^{(n)} | \mathbf{d}^{(n)}) &= p(\mathbf{d}^{(n)} | \mathbf{x}^{(n)}) \frac{p(\mathbf{x}^{(n)})}{p(\mathbf{d}^{(n)})} \\ &\approx \sum_{i=1}^N w_i^{(n)} \delta(\mathbf{x}^{(n)} - \mathbf{x}_i^{(n)}) \end{aligned} \quad (19)$$

where

$$w_i^{(n)} = \frac{p(\mathbf{d}^{(n)} | \mathbf{x}_i^{(n)})}{\sum_k p(\mathbf{d}^{(n)} | \mathbf{x}_k^{(n)})}. \quad (20)$$

Iterative application of these rules, where the posterior realizations in one time step are used as prior realizations in the next step, will approximately evolve the system in time according to the model equations and the uncertainties.

Resampling (sampling with replacement from the ensemble) is often used before each time step to obtain more equally weighted, but possibly duplicated particles.

Empirical Monte Carlo

Assume that N realizations from an unknown probability distribution $p(\mathbf{x})$ are available, and that we, for some reason, are unable to obtain more samples. We are interested in inferring information about a parameter of $p(\mathbf{x})$, for example, the distribution of its mean. This can be accomplished by an empirical Monte Carlo technique, for example, the resampling method *Bootstrapping* (Efron 1993):

Algorithm 10 Bootstrapping

To infer information about a parameter η of the distribution $p(\mathbf{x})$ from a set of realizations $A = \{\mathbf{x}_1, \dots, \mathbf{x}_N\}$, draw N elements from A with replacement (thereby allowing elements to be repeated) and compute η for the N elements. This process is repeated many times, each time obtaining a new value of η (if N is large). The normalized histogram for η of all these resampling experiments will be an approximation to the distribution of η .

Bootstrapping can in this way be used to evaluate biases, variances, confidence intervals, prediction errors, etc.

Monte Carlo Optimization

An important application of Monte Carlo algorithms is in the solution of complex optimization problems, for instance, in the location of the global minimum for an objective function $E(\mathbf{x})$. One of the first examples of a Monte Carlo optimizer was the following modification of the Metropolis-Hastings algorithm (6) (Kirkpatrick et al. 1983):

Simulated Annealing

Algorithm 11 (Simulated Annealing)

Given an objective function $E(\mathbf{x})$, a sequence of random numbers $U_n (n = 1, 2, \dots)$ in $[0, 1]$, a decreasing sequence of positive numbers (“temperature” parameters) $T_n \rightarrow 0$ for $n \rightarrow \infty$, and an iterative random function $V(\mathbf{x})$, sampling a constant probability density:

$$\mathbf{x}^{(n+1)} = V(\mathbf{x}^{(n)}). \quad (21)$$

Then the sample points produced by the iterative random function A :

$$\mathbf{x}^{(n+1)} = A(\mathbf{x}^{(n)}) = \begin{cases} V(\mathbf{x}^{(n)}) & \text{if } U_n \leq \min \left[1, \frac{\exp(-E(V(\mathbf{x}^{(n)}))/T_n)}{\exp(-E(\mathbf{x}^{(n)})/T_n)} \right], \\ \mathbf{x}^{(n)} & \text{otherwise} \end{cases} \quad (22)$$

asymptotically converge to the minimum of $E(x)$ as n goes to infinity.

This algorithm was inspired by the process of chemical annealing, where a crystalline material is slowly cooled ($T \rightarrow 0$) from a high temperature through its melting point, resulting in the formation of highly ordered crystals with low lattice energy E . In each step of the algorithm, thermal fluctuations in the system are simulated by the Monte Carlo algorithm (for applications, see Mosegaard and Vestergaard (1991) and Deutsch and Journal (1994)).

It is seen that, for constant temperature parameter T , the above algorithm is actually a Metropolis-Hastings algorithm designed to sample the Gibbs-Boltzmann distribution (see Mosegaard and Vestergaard 1991)

$$P_B(\mathbf{m}) = \frac{\exp\left(-\frac{E(\mathbf{m})}{T}\right)}{Z(T)} \quad (23)$$

Monte Carlo Optimization-Sampling Hybrids

The use of MCMC algorithms for inference often runs into problems in high-dimensional parameter spaces. When the target probability/objective function has multiple optima, MCMC algorithms show a critical slowing-down often making the analysis computationally intractable. There exist a few methods to alleviate this problem. Common to these methods is to use a “temperature” parameter to artificially increase (or vary) the noise to broaden the sampling density to hinder entrapment in local optima during sampling.

Parallel Tempering

One method is a simple modification of simulated annealing, where $E(\mathbf{x}) = -\ln(p(\mathbf{x}))$, and the decrease of T is stopped at $T = 1$ (see Salamon et al. (2002)). An inherent problem with simulated annealing is, however, the risk of entrapment in local minima for $E(\mathbf{x})$. The *parallel tempering* algorithm (Geyer 1991; Sambridge 2013), which is an improvement of an older algorithm *simulated tempering* (Marinari and Parisi 1992; Sambridge 2013), seeks to avoid the entrapment

problem by skipping the forced decrease of the “temperature” parameter T . The idea is to operate on an ensemble of models, and to include T in the parameters to be sampled:

Algorithm 12 (Parallel Tempering)

Given an ensemble $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_K)$ of K models, and their temperatures $T_1, T_2, \dots, T_K$, all distributed according to the same probability density p over the augmented spaces $(\mathbf{x}_k, T_k)$, $k = 1, 2, \dots, K$. The Metropolis-Hastings algorithm (6), with the special rule for V that any perturbation of T consists of swapping values of T for two random ensemble members, asymptotically samples the joint distribution $\prod_k p(\mathbf{x}_k, T_k)$, and the sample of ensemble members with $T_k = 1$ approaches a sample from the original target distribution $p(\mathbf{x})$.

If positive values of T close to $T^* \approx 0$ are allowed in this algorithm, the ensemble members with $T_k = T^*$ will be located close to the maxima for $p(\mathbf{x})$. In this way, parallel tempering can be used for optimization in a way similar to simulated annealing.

Other Approaches

Biological systems evolve by using a large population to explore many options in parallel, and this is the source of inspiration for evolutionary algorithms. An example of this is *genetic algorithms* (Holland 1975) where an ensemble $\mathbf{x}_1, \dots, \mathbf{x}_K$ of K sample points is assigned a probability $p(\mathbf{x}_k)$ of survival (“fitness”). In a simple implementation, the population is initially generated randomly, but at each iteration it is altered by the action of three operators: selection, crossover, and mutation. *Selection* randomly resamples the ensemble according to $p(\mathbf{x}_k)$, thereby typically duplicating ensemble members with high fitness at the expense of members with low fitness, improving the average fitness of the ensemble. The *crossover* step exchanges parameter values between two random members, and the *mutation* step randomly changes a parameter of one member. Crossover and mutation attempts are only accepted according to predefined probabilities. Iterative application of the above three steps allows the algorithm to asymptotically converge to a population with high fitness values $p(\mathbf{x}_k)$.

Another widely used technique is the neighborhood algorithm (Sambridge 1999a, b) where sample points are iteratively generated from a *neighborhood approximation* to the target distribution $p(\mathbf{x})$. The approximation is a piecewise constant function over Voronoi cells, centered at each of the previous sample points. The approximation to the target distribution is updated in each iteration, concentrating the sampling in multiple high-probability regions. The method will generate a distribution of points biased toward the maxima of $p(\mathbf{x})$.

Neither of the two algorithms above produces samples of the probability distribution p , but if supplemented with appropriate resampling of the output, an approximate sample from p may be produced.

Summary

We have given an overview of the use of Monte Carlo techniques for inference and optimization. A main theme behind the development of many methods has been to reduce the computational workload required to solve large-scale problems. Several ways of dealing with this challenge were discussed, including Markov-Chain Monte Carlo strategies, the use of sparse models, improving numerical forecast schemes through nonparametric representations of probability distributions, and even improving ideas inherited from early works on simulated annealing. Research in Monte Carlo methods is still a prolific area, and there is no doubt that many interesting developments are waiting ahead.

Synonyms

Moran I; Moran index; Moran's coefficient; Moran's I; Moran's ratio

Definition

Moran's index is a measure of spatial autocorrelation.

Introduction to Spatial Correlation Measures

Generally, the grade to which attributes or objects at some location on the earth's area are analogous to other attributes or objects in neighboring places is called spatial autocorrelation. The concept which Tobler has defined as the "first law of geography: everything is related to everything else, but near things are more related than distant things" (Tobler 1970), reflected the existence of the spatial autocorrelation.

As the name indicates, autocorrelation is the correlation between two variables of the same random field. If Z is the attribute observed in the plane, then the term spatial autocorrelation refers to the correlation between the same attribute at two spatial locations (Schabenberger and Gotway 2005).

Spatial analysis treats two quite different types of information. A first type of information is represented by the attributes of spatial characteristics, which comprise both measures (e.g., rainfall or population) and qualitative variables (e.g., name or type of soil). The other type of information is represented by the location of each spatial feature, which can be described by different geographical references or coordinate systems or by its position on a map (Goodchild 1986).

Spatial autocorrelation offers information about a phenomenon distributed in space, which can result essential for a right interpretation of the same phenomenon and which is not obtainable through other types of statistical analysis.

Moreover, in searching for a specific spatial distribution, it often occurs to find a variable which explains a pattern, but not completely. In this case, in order to identify any other variables that could be useful in explaining the remaining variation, the next stage is to examine the spatial model of residuals.

From the eventual absence of spatial autocorrelation in the residuals, it would be possible to deduce that (although the explanation of the model is not perfect) there would be little advantage in looking for further explicative variables, as they would be probably difficult and maybe singular to every sampling location.

As mentioned above, spatial autocorrelation is about comparing two types of information: similarity of location and similarity among attributes. The computation of the spatial proximity depends on the type of objects (points, areas, lines, rasters), while similarity among attributes can be measured in ways which depend on the type of data (interval, ordinal, nominal).

In the continuation, the following notation will be utilized:

- n : number of sampled objects;
- i, j : any two of the objects;
- w_{ij} : the similarity of i 's and j 's objects, where $w_{ii} = 0$ for all i ;
- z_i : the value of the attribute of interest for object i ;
- c_{ij} : the similarity of i 's and j 's attributes.

In general, the measures of spatial autocorrelation compare the set of attribute similarities c_{ij} with the set of locational similarities w_{ij} , combining them into a single index of the form $\sum_{i=1}^n \sum_{j=1}^n w_{ij} c_{ij}$, with properties which lead to quick interpretation.

Various methods have been proposed for estimating spatial proximity in order to create a suitable matrix of w_{ij} . Since the probability that objects are connected is greater for close ones than for distant ones, the existence of a connection between objects is often considered a measure of similarity of location. For example, a simple, indirect binary indicator of spatial proximity is represented by a common boundary between areas.

After obtaining the distances d_{ij} between objects i and j , in order to define the weights w_{ij} some appropriate decreasing function can be used. For example, a negative exponential $w_{ij} = \exp(-bd_{ij})$ or a negative power $w_{ij} = d_{ij}^{-b}$ can be used. In both cases a large b generates a quick decline and a small b a slower one. Indeed b represents a parameter affecting the speed at which weight decreases with spatial distance.

Various modes to assess the similarity of attributes have also been suggested, which are appropriate to the involved types of attributes.

For nominal data the usual approach is to set c_{ij} to 1 if i and j have the same attribute value, and 0 otherwise.

For ordinal data, similarity is usually based on comparing the ranks of i and j , while for interval data both the squared difference $(z_i - z_j)^2$ and the product $(z_i - \bar{z})(z_j - \bar{z})$ are commonly used.

Moran's Index

As previously mentioned, Moran's index (Moran 1948) is a measure of spatial autocorrelation.

In the following, some contexts characterized by different types of data and objects are discussed, as well as the respective possibility to apply spatial autocorrelation measures to them.

Interval Data and Area Objects

In the framework of interval data and area objects, the attribute similarity measure utilized by Moran's index makes it equivalent to a covariance between the values of a pair of objects $c_{ij} = (z_i - \bar{z})(z_j - \bar{z})$, where $\bar{z}$ denotes the mean of the attribute z values and c_{ij} measures the covariance between the value of the variable at one place and its value at another.

The remaining terms in Moran's index are designed to constrain it to a fixed range:

$$I = \frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} c_{ij}}{s^2 \sum_{i=1}^n \sum_{j=1}^n w_{ij}} \quad (1)$$

where the w_{ij} terms represent the spatial proximity of i and j and s^2 denotes the sample variance $s^2 = \sum_{i=1}^n (z_i - \bar{z})^2 / n$.

If neighboring areas tend to have similar attributes, the Moran index is positive. Conversely, if they tend to have more dissimilar attributes than might be expected, the Moran index is negative. Finally it is approximately null when attribute values are distributed randomly and independently in space.

Moran's index can be used alternatively to Geary's index for the identical application framework (area objects and interval attributes).

For a variable measured on an interval scale, in Geary's index (Geary 1968), attribute similarity c_{ij} is calculated with the squared difference in value $c_{ij} = (z_i - z_j)^2$. In the original paper (Geary 1954) the similarity of location was calculated in a binary way. If i and j had a common border, the weights w_{ij} could be set equal to 1. In the opposite case, the weights w_{ij} could be set equal to 0. The other terms in Geary's index guarantee that extremes happen at definite points:

$$c = \frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} c_{ij}}{2\sigma^2 \sum_{i=1}^n \sum_{j=1}^n w_{ij}} \quad (2)$$

where σ^2 denotes the variance of the attribute z values, that is, $\sigma^2 = \sum_{i=1}^n (z_i - \bar{z})^2 / (n-1)$. The value of c will be greater when large values of w_{ij} , which coincide with pairs of areas in contact, correspond to large values of c_{ij} , or large differences in attributes. As in Moran's index, the w_{ij} terms measure the spatial proximity of i and j and can be calculated by any suitable method.

In most applications Geary's and Moran's indices are satisfactory in the same way. However, Moran's index has the advantage that its extremes reflect the instinctive concepts of positive and negative correlation. Conversely, the scale used by Geary's index is not very clear as summarized in Table 1.

To explain the sense of the terms, the step-by-step computation of Moran's index can be represented in the following Example 1, using binary weights, as described above.

Example 1 Given the example of data set in Fig. 1, the step-by-step calculation of Moran's I is presented in the following.

$$n = 4 \quad \begin{matrix} z_1 = 1 \\ z_2 = 2 \\ z_3 = 2 \\ z_4 = 3 \end{matrix} \quad w = \begin{bmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix}$$

$$\bar{z} = \sum_{i=1}^n z_i / n = 8/4 = 2$$

Moran's Index, Table 1 Conceptual scales of spatial autocorrelation: correspondence between Geary's and Moran's indices

Conceptual scales	c index	I index
Similar	$0 < c < 1$	$I > 0^a$
Independent	$c = 1$	$I \simeq 0^a$
Dissimilar	$c > 1$	$I < 0^a$

^aThe correct expected value is $-1/(n-1)$ rather than 0

Moran's Index, Fig. 1 An example of data set for calculation of Moran's coefficient

$$c_{ij} = (z_i - \bar{z})(z_j - \bar{z}) \quad c = \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{bmatrix}$$

$$\sum_{i=1}^n \sum_{j=1}^n w_{ij} c_{ij} = -2$$

$$s^2 = \sum_{i=1}^n (z_i - \bar{z})^2 / n = 2/4 = 0.5$$

$$I = \frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} c_{ij}}{s^2 \sum_{i=1}^n \sum_{j=1}^n w_{ij}} = -2/0.5 \cdot 10 = -0.4.$$

Interval Data and Other Object Types (Point, Line, and Raster)

In the context of interval attributes, both Moran's index and Geary's index can also be used for other types of objects (point, line, and raster), as long as a proper way can be designed for assessing the geographical closeness of pairs of objects.

First of all it should be noted that one manner of creating a suitable w_{ij} measure for area objects consists in replacing each area by positioned control point and calculating distances. Then, to define the weights some appropriate decreasing function can be used. For example, a negative exponential or a negative power can be used, as said earlier. This indicates a simple method for accommodating both indices to point objects.

Another option would be to replace point objects with areas, using a systemic process; for example, the creation of Thiessen or Dirichlet polygons (Boots 1986). This procedure splits the total survey region into polygons. Each polygon encircles a point and envelopes the surface which is nearer to that point than any other. Relating to this it is suggested to see a powerful efficient way to creating Thiessen polygons from a point set (Brassel and Reif 1979), as well as a case showing the application of this procedure to evaluate spatial autocorrelation for point objects (Griffith 1982). As already mentioned, the weights could be defined on the basis of the existence of the common boundary or its length. In effect, areas and points can be considered replaceable for both Moran's and Geary's indices.

When the application context is characterized by line objects, it is possible to distinguish two different situations.

In the first case, the lines can represent connections between nodes; thus it is necessary to calculate the spatial

autocorrelation existing in some attribute observed at the nodal points, and the c_{ij} are measures of the similarity of the attributes of each pair of nodes, and the w_{ij} are measures of the links between them. For instance, the weight w_{ij} can be set equal to 1 if a direct link exists between i and j and 0 otherwise, or be based on the link capacity or length.

In the other situation, it is necessary to determine the spatial autocorrelation existing in some attribute observed at the links (for instance, probability of motor vehicle accident, or transport cost per unit length). In this case, the weight w_{ij} represents a measure of proximity between two links and might be defined according to the spatial distance between the central points of two links, or on whether or not two links are in direct connection. Therefore Geary's and Moran's indices represent proper measures for the interval attributes, even in the case of line objects, provided appropriate methods can be proposed for defining the spatial proximity measures.

For rasters (lattices) one simple way of defining the weights is to set w_{ij} equal to 1 if i and j have a common border and 0 in the opposite case. In some works two cells are considered to be adjacent, also when they join at a corner. When handling square rasters, the previous two cases are sometimes referred to as the Rook or 4-neighbor case and the Queen or 8-neighbor case, respectively (Lloyd 2010).

Ordinal Data

Several documents have treated the identification of particular spatial autocorrelation indices for ordinal attributes, namely attributes with ordinal scale of measurement. In particular, some experts have dealt with explaining the spatial distribution of the Canadian settlement sizes (Coffey et al. 1982). They wanted to investigate whether big settlements tended to be encircled by little settlements or by other big ones, or whether the size of settlements was casually distributed. In order to make the attribute an ordinal measure restricted to integers from 1 to 5, the settlements have been assigned to one of the five dimensional classes.

The authors proposed two kinds of spatial autocorrelation measures. In the first approach, the ordinal size class data are treated as having range properties, considering that the computation of Geary's and Moran's indices requires the difference between z values. Indeed, both the indices were calculated directly from the size classes by setting z_i equal to an integer between 1 and 5. The w_{ij} terms were set equal to 1 for pairs of settlements sharing a direct road link and 0 in the opposite case.

In the other approach, the set of measures is built on the recorded number of connections between settlements of different dimensional classes, and the ordinal data are treated as if they were merely nominal. For example, n_{23} would represent the count of direct road connections recorded between a

settlement belonging to class 2 and a settlement belonging to class 3. Then, the recorded number of every type of link was confronted with the number predicted, assuming a random distribution for settlement sizes. This type of measure is the issue of the following section.

On the other hand, some works described the index more directly suitable for ordinal data (Royaltey et al. 1975). Each object is given a rank based on its ordinal value, and the c_{ij} are then built on the absolute difference between ranks for each pair. The index was implemented to a set of points, using a procedure which created the matrix of weights called adjacency matrix of the Gabriel graph, obtained setting the weights equal to 1, if no other points were inside a circumference constructed with the pair of points as diameter and 0 alternatively (Gabriel and Sokal 1969). In addition, there was a further generalization of the index (Hubert 1978), and other indices for ordinal data, ever built on ranks, were discussed (Sen and Soot 1977).

Nominal Data

In the context of nominal attributes and for any type of objects (areas, points, lines, or raster) it is appropriate to think of them as a set of objects on the map colored using a limited collection of colors. If k indicates the number of possible attribute classes, the spatial distributions of the nominal data are usually referred to as k -color maps. Thus, a two nominal classes attribute could be imagined as a model of black and white, as good as a three nominal classes attribute could be viewed as a three-color distribution (red, yellow, and blue).

In dealing with nominal data the ways in which they can be compared represent a strong constraint, since no measures of difference are possible. The characteristics of the nominal data permit just two possibilities: two attributes can be the same or different. In constructing indices, then, the c_{ij} can take only one of two values.

In this context, many of the proposed measures are built on join count statistics, by defining w_{ij} in a binary way. Much of early work was in the context of raster data, in which if two cells have a common border, they can be considered as joined. Then the count of times that a color s cell results joined to a color t cell is defined as the join count between color s and color t (indicated with n_{st}). Moreover, in dealing with joins between cells having the same color, it is necessary to avoid double counting. Spatial autocorrelation measures can be based on join count statistics, as these reflected the spatial arrangement of colors. When the distribution exhibits positive autocorrelation the incidence of joins of the same color will be lower than would be expected assuming a casual distribution of colors. In the same way, if the distribution exhibits negative autocorrelation the incidence of joins between different colors will be higher than expected. Join count statistics are an easy

way to measure spatial model. However, they do not represent a summary index, and they are not similar to Geary's or Moran's measures.

The previous ideas can be extended from rasters to other types of objects, whenever analogous binary spatial proximity measures can be developed. Therefore, if two points share a Thiessen border, then they could be treated as united; if two lines share a common node, they could be considered adjacent; if two areas share a common border, they could be considered joined.

Conclusions

Spatial autocorrelation represents the correlation between the same attribute at two spatial locations, and it is about comparing two types of information: similarity among attributes and similarity of location. Moran's index is a measure of spatial autocorrelation for interval attributes and area objects. It uses the covariance between the value of the variable at one place and its value at another, as attribute similarity measure. Moran's index can be used alternatively to Geary's, which uses the squared difference in value, as attribute similarity measure for the same context (area objects and interval attributes). In most applications Geary's and Moran's indices are equally satisfactory. However, Moran's index has the advantage that its extremes reflect the instinctive concepts of positive and negative correlations. Conversely, the scale used by Geary's index is not very clear. In the context of interval attributes, in essence, both Moran's index and Geary's index can also be used for other types of objects (point, line, and raster), provided a proper way can be designed for assessing the geographical closeness of pairs of objects.

Several documents have treated the identification of particular spatial autocorrelation indices for ordinal attributes, and the authors proposed two kinds of spatial autocorrelation measures. In the first approach, the ordinal size class data are treated as having range properties, considering that the computation of Geary's and Moran's indices requires the differences between values. In the second approach, the ordinal data are treated as if they were merely nominal. On the other hand, some works described the index more directly suitable for ordinal data. Finally, for the nominal attributes, join count statistics represent an easy way to measure spatial model. However, they do not provide a summary index, and they are not similar to Geary's or Moran's measures.

Morphological Closing

Aditya Challa¹, Sravan Danda¹ and B. S. Daya Sagar²

¹Computer Science and Information Science, APPCAIR, BITS, Pilani, India

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Morphological closing is one of the basic operators from the field of Mathematical Morphology (MM). It is also one of the simplest morphological filters which is used for constructing more complex filters. And this operator is dual to morphological opening (chapter-ref). In general, morphological closing is defined as a composition of a dilation followed by an erosion. So, in case of discrete binary images, if X denotes

the binary image and B denotes the structuring element, morphological closing is defined as

$$\phi_B(X) = \varepsilon_B(\delta_B(X)) = (X \oplus B) \ominus B \quad (1)$$

This definition can be reduced to

$$\phi_B(X) = \cap \{B_x | X \subseteq B_x^c\} \quad (2)$$

Equivalently, in case of gray-scale images, if f denotes the gray-scale image and g denotes the structuring element, the closing is defined as

$$\phi_g(f) = \varepsilon_g(\delta_g(f)) \quad (3)$$

Illustrations

Morphological closing is one of the basic operators from the field of Mathematical Morphology. Its definition can be traced to fundamental works by Jean Serra (1983, 1988) and Georges Matheron (1975). In general, morphological closing is defined as a dilation operator composed with an erosion operator. In this entry, we illustrate the closing operator using binary images and discuss various properties. We also discuss the more general algebraic closings.

In simple words, (2) considers the intersection of all the translates of the structuring element whose complement would contain the original set. This is illustrated in Fig. 1. Here, the structuring element is taken to be a simple disk denoted by a dashed line in Fig. 1. All the points in the complement which do not fit within the structuring element are added to the original dataset. In Fig. 1, this corresponds to the spiked injection of the larger disk which gets filled.

Although not discussed here, similar intuition follows in gray-scale images as well (Dougherty and Lotufo 2003).

Some Important Properties

The properties of the closing operator are explained using the binary images. However, these properties easily extend to the

Morphological Closing, Fig. 1 Illustration of morphological closing. The shaded area refers to the set obtained by closing

gray-scale images as well. First, morphological closing is an *increasing operator*,

$$X \subseteq Y \Rightarrow \phi_B(X) \subseteq \phi_B(Y) \quad (4)$$

Moreover, it is also an *extensive operator*

$$X \subseteq \phi_B(X) \quad (5)$$

Also, the opening operator is idempotent

$$\phi_B(\phi_B(X)) = \phi_B(X) \quad (6)$$

Algebraic Closing

Morphological closing is a subset of a wider class of operators known as *Algebraic Closing*. An algebraic closing is defined as any operator on the lattice which is – (a) increasing, (b) extensive, and (c) idempotent. It is easy to see that morphological closing is a specific example of algebraic closing.

As an example of the algebraic closings which is not a morphological closing, consider the *Convex Closing* – take the smallest convex set which contains the given set. In Matheron (1975), it is shown that any algebraic closing can be defined as infimum of morphological closing.

Application to Filtering

Recall that, in the context of Mathematical Morphology, an operator which is increasing and idempotent is referred to as a *filter*. As stated earlier, morphological closing is one of the simplest filters based on which complex filtering operators such as top-hat transforms, granulometries, and alternating sequential filters are constructed, for instance, *Black top-hat* transform which is defined as

$$\text{BTH}(f) = \phi(f) - f \quad (7)$$

or simply $\text{BTH} = \phi - \mathbf{I}$ where $\mathbf{I}$ is the identity operator.

Summary

In this entry, morphological closing is defined for binary and gray-scale images. The practical utility of morphological closing is then illustrated using a simple binary image. The main properties of morphological closing namely increasing, extensiveness, and idempotence are then mentioned. A generalized notion of morphological closing, i.e., algebraic closing is defined. The entry is concluded by describing construction of more complex filter – black-top-hat transforms using morphological closing.

Morphological Dilation

Sravan Danda¹, Aditya Challa¹ and B. S. Daya Sagar²

¹Computer Science and Information Systems, APPCAIR, Birla Institute of Technology and Science, Pilani, Goa, India

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Morphological Dilation is one of the basic operators from the field of Mathematical Morphology (MM). Depending on the domain of application the definition varies. In the standard case of discrete binary images, given a binary image X , and a structuring element B the dilation of X is defined as

$$\delta_B(X) = \bigcup_{x \in X} B_x \quad (1)$$

where B_x denotes the structuring element translated by x . It is also a common practice to write $\delta_B(X) = X \oplus B$. Observe that the definition in (1) extends to continuous binary images as well.

In the case of gray-scale images, let f denote the gray-scale image and g denote the structuring function. Then, morphological dilation is defined by

$$\delta_g(f)(x) = \sup_{y \in E} \{f(y) + g(x - y)\} \quad (2)$$

where E denotes the domain of definition.

Both of the above definitions can be obtained from a general lattice-based definition of the dilation operator, as discussed in this entry.

Illustrations

Morphological dilation is one of basic operators from the field of mathematical morphology. Its definition can be traced to fundamental works by Jean Serra (1983, 1988) and Georges Matheron (1975). Depending on the domain the definition of the dilation operator differs (see Dougherty and Lotufo (2003)). However, all these definitions can be obtained from a generic lattice-based definition. In this entry, we discuss the morphological dilation in specific case of discrete binary and gray-scale images. We then provide the generic lattice-based definition and show how this reduces to the definitions in discrete binary and gray-scale images.

Binary Images

The procedure to construct the dilation of a discrete binary image X is illustrated in Fig. 1. 0 values are not indicated in the image. Given the discrete binary image X and the structuring element B , we proceed by translating and placing B at all possible positions of X , as shown in Fig. 1. The final dilated image is obtained by taking the union of all these translations. In mathematical terms, this corresponds to (1).

One can also construct the dilation of a discrete binary image X by translating the image X for all possible values b in B , and then taking the union of these translations. In mathematical terms, this corresponds to

Morphological Dilation, Fig. 1 Illustration of morphological dilation

$$\delta_B(X) = \bigcup_{b \in B} X_b \quad (3) \quad \text{Observe that, in the case of flat structuring element, we have}$$

This is equivalent to the definition in (1).

$$\delta_g(f)(x) = \sup_{y \in E} \{f(y) + g(x-y)\} = \sup_{(x-y) \in K} \{f(y)\} \quad (4)$$

Gray-Scale Images

In the case of gray-scale images, structuring element g is a function as well. It is usually the practice that g is only defined on a finite/compact subset K of the domain. If, on the finite/compact subset, g only takes the value 0, it is referred to as the *flat structuring element*, else it is referred to as *non-flat structuring element*.

where K denotes the finite/compact set on which g is defined. That is, the dilated value is taken to be the maximum over a neighborhood. This is illustrated in Fig. 2. We consider a generic gray-scale image f . In gray-scale images, it is a convention that the values in the flat structuring element are taken to be 0 over the domain of definition and empty when it is not defined. As in the case of binary images, the structuring element is translated to each position of the original image. Within each neighborhood,

Morphological Dilation, Fig. 2 Illustration of morphological dilation with gray-scale images

is considered, and the central value is replaced by this maximum value. Finally, the maximum over all these images is taken. At the boundaries, only the values that exist in the domain are considered.

In the case of non-flat structuring element, the values of g are added to the neighborhood values and then the maximum is computed.

Remark: Recall that the gray-scale images can take the values in $\{0, 1, 2, \dots, 255\}$. However, it is possible that in definition (2) the right-hand-side value may be higher than 255. In such cases, we take any value greater than 255 to be 255.

Some Important Properties

The properties of the dilation operator are explained using the binary images. However, these concepts extend to the gray-scale images as well. Firstly, morphological dilation is an *increasing operator*,

$$X \subseteq Y \Rightarrow \delta_B(X) \subseteq \delta_B(Y) \quad (5)$$

Moreover, it is also an *extensive operator* when the structuring element B is symmetric and the center belongs to B .

$$X \subseteq \delta_B(X) \quad (6)$$

Also, dilation can be thought to be *commutative*

$$\delta_B(X) = \delta_X(B) \quad (7)$$

Lattice-Based Definition

Recall that a *partially ordered set* is a set $\mathcal{L}$ with a binary order $\leq$ such that: (i) $x \leq x$ (reflexivity) – (ii) $x \leq y$ and $y \leq x$ implies $x = y$ (anti-symmetry), and (iii) $x \leq y$ and $y \leq z$ implies $x \leq z$ holds true. A partially ordered set is called a *lattice* when any finite subset of $\mathcal{L}$ has an infimum and a supremum. It is called a *complete lattice* if any subset of $\mathcal{L}$ has an infimum and a supremum.

The dilation operator on a complete lattice is defined as an operator $\delta: \mathcal{L} \rightarrow \mathcal{L}$ which

- is increasing, i.e., $x \leq y$ implies $\delta(x) \leq \delta(y)$,
- preserves the supremum, i.e., $\delta(\bigvee_{i \in I} x_i) = \bigvee_{i \in I} (\delta(x_i))$.

In case the index set I is empty, we have $\delta(\mathbf{0}) = \mathbf{0}$, where $\mathbf{0}$ denotes the infimum of $\mathcal{L}$.

How Does This Definition Relate to Definitions in (1) and (2)?

In case of discrete binary images, the complete lattice is taken to be the power set, i.e., $\mathcal{L} = \mathcal{P}(E)$ where E denotes the domain of definition for the binary images. The infimum/supremum of any subset is obtained by intersection/union, respectively. Assume that $\delta(\{0\}) = B$, i.e., the set $\{0\}$ maps a set B in the lattice. Using *invariance w.r.t translation*, we get

$$\delta(\{x\}) = \delta(T_x(\{0\})) = T_x(\delta(\{0\})) = T_x(B) = B_x \quad (8)$$

Where T_x is a translation operator, which translates all elements by x , and B_x denotes the set B , which is translated by x as usual. Now, to obtain the dilation of a generic set X , we have

$$\delta(X) = \delta(\bigvee_{x \in X} x) = \bigvee_{x \in X} (\delta(x)) = \bigvee_{x \in X} B_x = \bigcup_{x \in X} B_x \quad (9)$$

which is identical to the definition of dilation one has in discrete binary images.

In case of discrete gray-scale images, the lattice is obtained by the set of all possible functions $f: E \rightarrow \{0, 1, 2, \dots, 255\}$ where E is the domain of definition for the image. The binary images can be thought “of” as a specific case where $f: E \rightarrow \{0, 1\}$ alone. Define

$$f_1 \leq f_2 \Leftrightarrow f_1(x) \leq f_2(x) \text{ for all } x \in E \quad (10)$$

The infimum of two functions is given by

$$(f_1 \wedge f_2)(x) = (f_1(x) \wedge f_2(x)) \quad (11)$$

and the supremum is given by

$$(f_1 \vee f_2)(x) = (f_1(x) \vee f_2(x)) \quad (12)$$

Now, observe that if E is finite, then the set of all possible functions as above is a complete lattice, $\mathcal{L}$. Consider the set of functions e_i defined as

$$e_{v,z}(x) = \begin{cases} 0 & \text{if } x \neq z \\ v & \text{if } x = z \end{cases} \quad (13)$$

Observe that any function f can be written as

$$f = \bigvee \{e_{v,z} | e_{v,z} \leq f\} \quad (14)$$

So, if one defines the dilation operator on $e_{v,z}$, then from the law of preserving the supremum we obtain the dilation for f .

Moreover, assuming the translation to invariance in the domain, one needs to define the dilations for cases of $e_{v,0}$ where 0 denotes the origin. For each of these functions we assume that the dilation is obtained by

$$\delta(e_{v,0}) = e_{v,0} + g \quad (15)$$

So, we have

$$\delta(f) = \delta(\vee\{e_{v,z} | e_{v,z} \leq f\}) \quad (16)$$

$$= \vee(\{\delta(e_{v,z}) | e_{v,z} \leq f\}) \quad (17)$$

$$= \vee(\{\delta(e_{v,0}) | e_{v,0} \leq T_{-z}(f)\}) \quad (18)$$

$$= \vee(\{e_{v,0} + g | e_{v,0} \leq T_{-z}(f)\}) \quad (19)$$

$$= \vee(\{T_{-z}(f) + g\}) \quad (20)$$

The second equality follows since dilation preserves the supremum. The third equality follows from translation to invariance. That is, if $e_{v,z}(x) < f(x)$, then we have $e_{v,0} < f(x - z)$. Simply substituting the dilation definition gives the fourth equality. The final equality follows from noting that $\vee e_{v,0} \leq T_{-z}(f) = T_{-z}(f)$. Now, the final equation for a specific $x \in E$ can be written as

$$\delta(f)(x) = \vee(\{f(x - z) + g(x)\}) \quad (21)$$

This is identical to the gray-scale definition we have in (2).

Summary

In this entry, morphological dilation is defined in the context of binary and gray-scale images. These definitions are then illustrated on fictitious images. Several types of structuring elements that are intrinsic to the definition of a morphological dilation are described. The main properties of morphological dilation – increasing, extensive, and commutative – are discussed. The definition of morphological dilation in lattices is then described in detail.

Definition

Morphological erosion is one of the four basic operators from the field of Mathematical Morphology (MM). This is a dual operator to morphological dilation. Depending on the domain of application, the definition varies. In the standard case of discrete binary images, given a binary image X , and a structuring element B (cross-ref), the erosion of X is defined as

$$\epsilon_B(X) = \bigcap_{b \in \hat{B}} X_b \quad (1)$$

Here $\hat{B}$ denotes the reflection of $B - x \in B \Leftrightarrow -x \in \hat{B}$. X_b denotes the image X translated by b for each b belonging to the $\hat{B}$. It is also a common practice to write $\epsilon_B(X) = X \ominus B$. Observe that the definition in (1) extends to continuous binary images as well.

In the case of gray-scale images, let f denote the gray-scale image and g denote the structuring function. Then, morphological erosion is defined by

$$\epsilon_g(f)(x) = \inf_{y \in E} \{f(y) - g(x - y)\} \quad (2)$$

where E denotes the domain of definition.

These definitions can be derived from the fact that erosion is dual to dilation using the definition of dilation.

Illustrations

Morphological erosion is one of the basic operators from the field of mathematical morphology. Its definition can be traced to fundamental works by Jean Serra (1983, 1988) and Georges Matheron (1975). Depending on the domain, the definition of the erosion operator differs Dougherty ER, Lotufo RA (2003). However, all these definitions can be obtained from a generic lattice-based definition. In this entry, we discuss morphological erosion in specific case of discrete binary and gray-scale images. We then provide the derivation of these definitions from the lattice-based definitions.

Binary Images

The procedure to construct the erosion of a discrete binary image X is illustrated in Fig. 1. Zero values are not indicated in the image. Given the discrete binary image X and the structuring element B , we proceed by translating X by $-b$ for all possible values in B , as shown in Fig. 1. The final eroded image is obtained by taking the intersection of all these translations. In mathematical terms, this corresponds to (1).

Gray-Scale Images

In the case of gray-scale images, structuring element g is a function as well. It is usually the practice that g is only defined on a finite/compact subset K of the domain. If, on the finite/compact subset, g only takes the value 0, it is referred to as the

Morphological Erosion, Fig. 1 Illustration of morphological erosion

flat structuring element, else it is referred to as nonflat structuring element.

Observe that in the case of flat structuring element, we have

$$\epsilon_g(f)(x) = \inf_{y \in E} \{f(y) - g(x-y)\} = \inf_{(x-y) \in K} \{f(y)\} \quad (3)$$

where K denotes the finite/compact set on which g is defined. That is, the eroded value is taken to be the minimum over a neighborhood. This is illustrated in Fig. 2. We consider a generic gray scale image f . In gray-scale images, it is a convention that the values in the flat structuring element are taken to be 0 over the domain of definition and empty when they are not defined. As in the case binary images, the structuring element is translated to each position of the original

image. Within each neighborhood, the maximum is considered, and the central value is replaced by maximum values. Finally, the minimum over all these images is taken. At the boundaries, only the values which exist in the domain are considered.

In the case of the nonflat structuring element, the values of g are added to the neighborhood values and then the minimum is computed.

Some Important Properties

The properties of the erosion operator are explained using the binary images. However, these properties could extend to the gray-scale images as well. Most of these properties can be derived from noting that the erosion operator is dual to the

Morphological Erosion, Fig. 2 Illustration of morphological dilation with gray-scale images

dilation operator. First, morphological erosion is *increasing operator*,

$$X \subseteq Y \Rightarrow \epsilon_B(X) \subseteq \epsilon_B(Y) \quad (4)$$

Moreover, it is also an *antiextensive operator* when the structuring element B is symmetric.

$$X \supseteq \epsilon_B(X) \quad (5)$$

Lattice-Based Definition

Recall that a *partially ordered set* is a set $\mathcal{L}$ with a binary order $\leq$ such that: (i) $x \leq x$ (reflexivity), (ii) $x \leq y$ and $y \leq x$ implies $x = y$ (antisymmetry); and (iii) $x \leq y$ and $y \leq z$ imply $x \leq z$ holds true. A partially ordered set is called a lattice when any finite subset of $\mathcal{L}$ has an infimum and a supremum. It is called a complete lattice if any subset of $\mathcal{L}$ has an infimum and a supremum.

The erosion operator on a complete lattice is defined as an operator $\epsilon : \mathcal{L} \rightarrow \mathcal{L}$ which

- Is increasing, i.e., $x \leq y$ implies $\epsilon(x) \leq \epsilon(y)$
- Preserves the infimum, i.e., $\epsilon(\bigwedge_{i \in I} x_i) = \bigwedge_{i \in I} (\epsilon(x_i))$

In case the index set I is empty, we have $\epsilon(\mathbf{m}) = \mathbf{m}$, where $\mathbf{m}$ denotes the supremum of $\mathcal{L}$.

How Does This Definition Relate to Definitions in (1) and (2)?

The optimal approach to deriving equations (1) and (2) is by using the *duality* property, i.e.,

$$\epsilon(x) = (\delta(x^c))^c \quad (6)$$

where x^c denotes the complement of x in the lattice $\mathcal{L}$. Observe that the definition of the erosion can in fact be derived starting from the duality principle. In the chapter of morphological dilation (chapter-ref), we derived the specific definition from the lattice definitions. Here, we shall use the duality property to arrive at definitions (1) and (2).

In case of binary images, we have the duality by complement operation. It has already known that

$$\delta_B(X) = \bigcup_{x \in X} |B_x = \bigcup_{b \in B} X_b \quad (7)$$

So using duality by complementation, we have

$$\epsilon_B(X) = (\delta_B(X^c))^c = \left(\bigcup_{b \in B} (X^c)_b \right)^c \quad (8)$$

$$= \left(\bigcap_{b \in B} X_b \right) \quad (9)$$

As a convention, if B is the structuring element used for dilation, then $\hat{B}$, the reflection of the structuring element, is used for erosion. Accordingly, a reflection operation is embedded into the definition of the erosion to obtain (1). This is because, only if the structuring element B is reflected, would (δ_B, ϵ_B) form an adjunction, i.e.,

$$\delta_B(X) \leq y \Leftrightarrow x \leq \epsilon_B(y) \quad (10)$$

Adjunction is an important property for defining morphological opening

In the case of gray-scale images, the duality is obtained by inversion

$$\epsilon_g(f) = 255 - \delta_g(255 - f) \quad (11)$$

Then we have,

$$\epsilon_g(f) = 255 - \delta_g(255 - f) \quad (12)$$

$$= 255 - \sup_{y \in E} \{255 - f(y) + g(x - y)\} \quad (13)$$

$$= \inf_{y \in E} \{255 - (255 - f(y) + g(x - y))\} \quad (14)$$

$$= \inf_{y \in E} \{f(y) - g(x - y)\} \quad (15)$$

which is equivalent to definition in (2).

The lattice-based definitions are much more general, and the specific definitions can be derived from here.

Summary

In this chapter, morphological erosion is defined in the context of binary and gray-scale images. These definitions are then illustrated on simple examples. Several types of structuring elements which are intrinsic to the definition of a morphological erosion are described. The main properties of morphological erosion – increasing and antiextensive – are discussed. The definition of morphological erosion in lattices is then described in detail.

Morphological Filtering

Jean Serra

Centre de morphologie mathématique, Ecoles des Mines, Paristech, Paris, France

Definition

An operation which maps a complete lattice into itself is said a *morphological filter* when it is increasing and idempotent. Morphological filtering is mainly used for binary and vector images, and for partitions. When a connection, or a connectivity, is involved, morphological filtering allows to segment images, i.e., to find contours for the objects. Moreover these filters often depend on a size parameter which orders them in a hierarchy and from which one extracts the optimal segmentation.

Morphological Filters

In physics or in chemistry, when one says that one filters a precipitate, one describes in some way an opening. However this meaning is not the only one. In signal processing, one usually means by filter any *linear* operator that is *invariant under translation* and *continuous*. According to a classical result, every filter in the previous sense is expressed as the convolution product $F * \varphi$ of the signal F by a convolution distribution φ , and the transform of $F + F'$ is the sum of the transforms of F and of F' . If you listen on the radio to a duet for piano and violin, it is quite natural that the amplified sound should be the sum of the amplifications from the piano alone and from the violin alone.

To the three axioms of convolution, a fourth one is in fact added: it is in practice very common to consider filters as being of the band-pass type, even if that is not quite exact. One says about a Hi-Fi amplifier that it is “low-pass up to 30 000 Hz”, of a tainted glass that it is monochromatic, etc. In this doing, one attributes implicitly to the operation of filtering the property of not being able to act by iteration: the signal that has lost its frequencies above 30,000 Hz will not be modified further if one submits it to a second amplifier identical to the first. We find again idempotence, which however is not captured by the axioms of convolution.

This approach, based on linear filtering, is very well adapted to telecommunications, where the fundamental problem is the pass band of the channel, which requires to modify consequently the frequency band of the signal. But in geosciences and in image analysis, what matters is not to recognize frequencies, but to detect, localize and measure objects. One must thus be able to express spatial relations between objects, the first one being *inclusion*, which induces the lattice framework, where growth replaces the linearity of vector spaces. Since furthermore complete lattices lend themselves very well to taking into account idempotence, we are led to define as a morphological filter as follows:

Definition *Given a complete lattice $\mathcal{L}$, one calls a morphological filter, or more briefly a filter, any operator $\psi : \mathcal{L} \rightarrow \mathcal{L}$ that is both increasing and idempotent.*

Openings and closings, that we already met in the article ► [“Mathematical Morphology”](#), illustrate this notion, but one can devise many other filters. For example, we can think of these two operations as primitives and combine them serially or in parallel to create new filters. The first mode, by composition products leads to the alternating (sequential) filters, and the second one to the lattice of filters. Remark that translation invariance is never a prerequisite, the filters may vary from place to place, according to the context.

Products of Filters

When ψ and ξ are two ordered filters, that is, $\psi < \xi$, the inequalities

$$\psi\xi \leq \psi\psi\xi \leq \psi\xi\psi\xi \leq \psi\xi\xi\xi \leq \psi\xi$$

show that the product $\psi\xi$ is in turn a filter.

For the sake of concision, let us write $\mathcal{B}_\alpha$ for the invariance domain $\text{Inv}(\alpha)$ of a filter α . One can state the:

Matheron’s Criterion (Matheron 1988)

Let ψ and ξ be two filters such that $\psi \leq \xi$. Then:

1. Their products generate only the four filters $\psi\xi$, $\psi\xi\psi$, $\xi\psi\xi$, and $\xi\psi$ that are partly ordered:

$$\psi \leq \psi \xi \psi \leq \left\{ \begin{matrix} \xi \psi \\ \psi \xi \end{matrix} \right\} \leq \xi \psi \xi \leq \xi.$$

$\xi \psi \xi$ is the least filter above $\xi \psi \vee \psi \xi$, and $\psi \xi \psi$ is the greatest filter below $\xi \psi \vee \psi \xi$.

2. Although the product $\xi \psi$ is not commutative in general, each filter $\xi \psi$ or $\psi \xi$ eliminates positive noise and sharp reliefs, as well as negative noise and narrow hollows. When the two primitive are an opening γ and a closing φ , which is the most popular case, then the two four products $\gamma \varphi$ and $\varphi \gamma$ have the following characteristic property:

$$f \leq g \leq f \vee \gamma \varphi(f) \implies \gamma \varphi(g) = \gamma \varphi(f)$$

and similarly $f \wedge \varphi \gamma(f) \leq g \leq f \implies \varphi \gamma(g) = \varphi \gamma(f)$. The first property ensures that any signal g between f and $f \vee \gamma \varphi(f)$ gives the same filtered version as f itself. The second one is the dual version for $\varphi \gamma$.

Iterations of Over and Underfilters

We just saw how to generate filters by composition products. Is it also possible to obtain filters by suprema or infima? The supremum $\bigvee_{i \in I} \psi_i$ (respectively, the infimum $\bigwedge_{i \in I} \psi_i$) of a family $\{\psi_i \mid i \in I\}$ of filters is visibly overpotent (respectively, underpotent), that is, $\psi^2 \geq \psi$ (respectively $\psi^2 \leq \psi$), which makes it lose the idempotence that the ψ_i had. One can nevertheless speak of a lattice of filters (Matheron 1988).

Put $\bigvee_{i \in I} \psi_i = \alpha$. When $\mathcal{L}$ is finite, we always reach $\alpha^{n+1} = \alpha^n$ for n large enough; it suffices to iterate the overpotent operator α to obtain finally the idempotent limit $\Phi(\alpha) = \alpha^n$ which turns out to be the least filter above all the ψ_i . When $\mathcal{L}$ is infinite, $\alpha, \alpha^2, \dots, \alpha^n$ and $\bigvee_{n \in \mathbb{N}} \alpha^n$ are still overpotent, but $\bigvee_{n \in \mathbb{N}} \alpha^n$ is not necessarily idempotent; it will be if α is $\uparrow$ -continuous. Dually, we put $\bigwedge_{i \in I} \psi_i = \beta$. If the lattice $\mathcal{L}$ is finite, or if β is $\downarrow$ -continuous, then $\bigwedge_{n \in \mathbb{N}} \beta^n$ will be the greatest filter $\Gamma(\beta)$ below all the ψ_i . Let us also remark that in some cases one of the terms, Φ or Γ , is obtained directly, but not the other: for example, when the ψ_i are openings ψ_i , the supremum $\Phi(\bigvee_{i \in I} \gamma_i) = \bigvee_{i \in I} \gamma_i$, but the infimum $\Gamma(\bigwedge_{i \in I} \gamma_i)$ requires iterations.

Hierarchies and Semigroups

By regard for pedagogy, until now we have not parameterized the filters. To make them depend upon a parameter $\lambda > 0$ of scale or size, leads us to ponder the structure of the obtained family $\{\Psi_\lambda \mid \lambda \geq 0\}$. For example, is the product $\Psi_\mu \Psi_\lambda$ of two of the filters in the family? If the increasing λ correspond to stronger and stronger simplifications, can one start from any intermediate level $\Psi_\mu(A)$ to reach $\Psi_\lambda(A)$, when $\mu < \lambda$? For answering these questions, we can firstly examine the openings γ and the alternating filters $\gamma \varphi$.

Granulometries

The case of openings is the simplest. Following G. Matheron, we will say that the family $\{\gamma_\lambda \mid \lambda \geq 0\}$ with a positive parameter generates a *granulometry* when:

1. For every $\lambda \geq 0$, the operator γ_λ is an opening, with $\gamma_0 = \text{id}$
2. In the composition product, the most severe opening imposes its law:

$$\gamma_\mu \gamma_\lambda = \gamma_{\max\{\lambda, \mu\}}. \quad (1)$$

In terms of sifting, the grains refused by a sieve will be *a fortiori* by sieves with smaller holes. This second axiom amounts to saying that the openings decrease when the parameter increases, that is, $\lambda \geq \mu \geq 0 \implies \gamma_\lambda \leq \gamma_\mu$, or as well that their invariance domains decrease, that is, $\lambda \geq \mu \geq 0 \implies \mathcal{B}_\lambda \subseteq \mathcal{B}_\mu$. By duality, one constructs in a similar way the anti-granulometry $\{\varphi_\lambda \mid \lambda \geq 0\}$.

The two axioms of Matheron model the sieving technique, where solid particles are classified according to a series of sieves with decreasing meshes. They describe, similarly, the sizes of the individuals in a population. But they also apply to procedures which are not based on individual particles, like the Purcell method used in the petroleum industry, where mercury is injected into specimen of porous rocks under various pressures. Or again they model the linear intercept distributions in image analysis, the disc openings, etc.

The relation (1) defines a commutative semigroup, with the identity **id** as neutral element, called the Matheron semigroup, whose use extends well beyond the granulometric case of openings.

In particular, in the Euclidean case with invariance under translation, this relation weaves a link between granulometry by adjunction, similarity, and convexity. Indeed, every λB homothetic to the compact B is open by adjunction by μB for every $\mu \geq \lambda$ if and only if B is convex, and consequently the family $\{\gamma_{\lambda B} \mid \lambda \geq 0\}$ of openings by the convex sets $\{\lambda B \mid \lambda > 0\}$ is granulometric. Here, the hypotheses of convexity or similarity are equivalent. On the other hand, if one does not impose similarity, then the $B(\lambda)$ do not need to be convex, nor even connected.

Alternating Sequential Filters

Let us proceed to the products of the type $\varphi \gamma$, or $\gamma \varphi$, of an opening by a closing. To parameterize directly the two primitives leads to a rather coarse result, that one refines by replacing the primitives by a granulometry $\{\gamma_\lambda \mid \lambda \geq 0\}$ and an anti-granulometry $\{\varphi_\lambda \mid \lambda \geq 0\}$. Let us suppose for the moment λ a positive integer, and set:

$$\varpi_n = \varphi_n \gamma_n \cdots \varphi_2 \gamma_2 \varphi_1 \gamma_1.$$

The operator ϖ_n is a filter, designated as *alternating sequential* (or *ASF*), and due to S.R. Sternberg. Although it

Morphological Filtering, Fig. 1 Left: initial mosaic; other views, from left to right: connected ASF of sizes $\lambda = 1, 4, 6$

is constructed in view of the semigroup, it does not satisfy Eq. (1), but only the *absorption law*.

$$p \geq n \Rightarrow \varpi_p \varpi_n = \varpi_p,$$

which is sufficient to construct hierarchies of more and more severe ASF. Nevertheless, when the γ_λ and φ_γ , $\lambda \geq 0$, are *grain operators*, that is, families of connected openings (respectively, closings) that process each grain (respectively, pore) independently from the others, then the associated ASF ϖ_n form a Matheron semigroup Serra (2000). An example is given in Fig. 1. The γ_i are connected openings by reconstruction from the eroded initial image by a disc of radius λ , and the φ_i are the dual operators. Each contour is preserved or suppressed, but never deformed: the initial partition increases under the successive filters, which form a Matheron semigroup.

When λ is a positive real, one often subdivides the segment $[0, \lambda]$ into $2, 4, \dots, 2^k, \dots$ sections of filters $\varpi_k(\lambda) = \varphi_\lambda \gamma_\lambda \cdots \varphi_{i2^{-k}\lambda} \gamma_{i2^{-k}\lambda} \cdots \varphi_0 \gamma_0$, with $0 \leq i \leq 2^k$. When k increases, the $\varpi_k(\lambda)$ decrease, and $\bigwedge_k \varpi_k(\lambda) = \varpi(\lambda)$ still remains a filter Serra (1988) p.205. The preceding properties extend to that continuous version. Finally, what has been said here for the sequences of primitives $\varphi_\lambda \gamma_\lambda$ remains true if one starts with from $\gamma_\lambda \varphi_\lambda$.

Connections

In image processing, the fundamental operation associated with connectivity consists in directing a point towards a set and extracting the marked particle. The result depends on the choice of the said connectivity (e.g., 4- or 8-connectivities in square grid), but in all cases, the particles of a set A pointed at x and at y are either identical, or disjoint, for all x and y of the space. Moreover, the operation which goes from A to its connected component in x is obviously an opening. Besides, connected zones that intersect are included in a same connected component. These characteristics can be

summarized in the following axiomatics (Serra 1988) p.51. Let E be an arbitrary space:

- A *connection* on $\mathcal{P}(E)$ is a family $\mathcal{C} \subseteq \mathcal{P}(E)$ that satisfies the following three conditions:
 1. $\emptyset \in \mathcal{C}$.
 2. $\forall p \in E, \{p\} \in \mathcal{C}$.
 3. $\forall \{C_i | i \in I\} \subseteq \mathcal{C}, \bigcap_{i \in I} C_i \neq \emptyset \Rightarrow \bigcup_{i \in I} C_i \in \mathcal{C}$.
 An element of $\mathcal{C}$ is called *connected*.
- A *system of connection openings* on $\mathcal{P}(E)$ associates with each point $p \in E$ an opening γ_p on $\mathcal{P}(E)$ that satisfies the following three conditions, $\forall p, q \in E$:
 1. $\gamma_p(\{p\}) = \{p\}$.
 2. $\forall X \in \mathcal{P}(E), \gamma_p(X) \cap \gamma_q(X) \neq \emptyset \Rightarrow \gamma_p(X) = \gamma_q(X)$.
 3. $\forall X \in \mathcal{P}(E), p \notin X \Rightarrow \gamma_p(X) = \emptyset$.

For $p \in X$, $\gamma_p(X)$ is referred to as the *connected component* of X marked by p .

The two notions are indeed equivalent (Serra 1988) p.52, as shown by the following theorem:

Theorem

There exists a bijection between the connections on $\mathcal{P}(E)$ and the systems of connection openings on $\mathcal{P}(E)$:

- with a connection $\mathcal{C}$ one associates the system of connection openings $(\gamma_p, p \in E)$ defined for all $X \in \mathcal{P}(E)$ by:

$$\gamma_p(X) = \bigcup \{C \in \mathcal{C} | p \in C \subseteq X\}; \quad (2)$$

- with a system of connection openings $(\gamma_p, p \in E)$ one associates the connection $\mathcal{C}$ defined by:

$$\mathcal{C} = \{\gamma_p(X) | p \in E, X \in \mathcal{P}(E)\}. \quad (3)$$

Classically in topology, a set is connected when it cannot be partitioned into two non-empty closed (or open) regions. In topology, one also speaks of arcwise connectivity, according

to which a set A is connected when for each pair of points $a, b \in A$, one can find a continuous map ψ from $[0, 1]$ into A such that $\psi(0) = a$ and $\psi(1) = b$. This last connectivity is more restrictive than the first one, though in R^n both notions coincide on the open sets. In discrete geometry, the digital connectivities are particular cases of graph connectivity, which transposes to arcs the Euclidean arcwise definition. In Z^2 one then finds, among others, the classical 4- and 8-connectivities of the square grid and the 6-connectivity of the hexagonal grid; and in Z^3 the 6- and 26-connectivities of the cube, or that of the cube-octahedron.

All these topological or digital connectivities satisfy the axiomatics of connections. But the latter does not presuppose any topology, or the distinction between continuous and discrete approaches. It is thus more comprehensive, and also better adapted to image processing, as it starts from one of its basic operations. The axiomatic of a connection has been relaxed by C. Ronse, by suppressing the axiom about the points (Ronse 2008), and by M. Wilkinson by extending it to ultra-connections which allow some covering (Wilkinson 2006).

Examples of Connections

We now describe two examples of connections taken among many other ones (Ronse 2008; Serra 1988). Both are often used in practice and cannot be reduced to usual connectivities.

Connection by dilation Start from a set $\mathcal{P}(E)$ which is already provided with a connection C and consider an extensive dilation $\delta : \mathcal{P}(E) \rightarrow \mathcal{P}(E)$ which preserves C , i.e., $\delta(C) \subseteq C$; equivalently, it is required that $\forall p \in E, p \in \delta(p) \in C$. Then the inverse image $C' = \delta^{-1}(C)$ of C by δ constitutes a second connection, richer than C , i.e., $C' \supseteq C$. For all $A \in \mathcal{P}(E)$, the C -components of $\delta(A)$ are exactly the images by δ of the C' -components of A . If γ_x stands for the opening associated with C , and v_x for that associated with C' , we have:

$$\delta v_x(A) = \gamma_x \delta(A) \cap A \quad \text{if } x \in A, \quad v_x(A) = \emptyset \quad \text{otherwise.}$$

If, in the Euclidean or digital plane, we take for example for δ the dilation by a disc of radius r , then the openings γ_x

characterize the clusters of objects whose *infimum* of the distances between points is $\leq 2r$ (Fig. 2, right). *A contrario*, the same approach extracts also the isolated connected components in a set A , since they specifically satisfy the equality $v_x(A) = \gamma_x(A)$.

Connection induced by a partition Consider a given partition D , and a point $x \in E$. The operation which associates, with each $A \subseteq E$, the transform

$$\gamma_x(A) = D(x) \cap A \quad \text{if } x \in A, \quad \gamma_x(A) = \emptyset \quad \text{otherwise.}$$

is clearly an opening, and as x varies, the $\gamma_x(A)$ and $\gamma_y(A)$ are identical or disjoint because they correspond to classes of partitions. The class:

$$C = \{\gamma_x(A) | x \in E, A \in \mathcal{P}(E)\}$$

is thus a connection. One sees in Fig. 2 (left) that C breaks the usual connected components, and puts together their pieces when they lie in a same class $D(x)$. If E has been provided with a prior connection C' , like the usual arcwise one, then the elements of $C \cap C'$ are the connected components in the sense of C' of the intersections $A \cap D(x)$.

A few properties of connections are as follows:

1. *Lattice*: The set of all connections on E is a complete lattice, where the *infimum* of the family $\{C_i | i \in I\}$ is the intersection $\bigcap_{i \in I} C_i$, and the *supremum* is the least connection containing $\bigcup_{i \in I} C_i$.
2. *Maximum partitioning*: The openings γ_x of connection C partition every set $A \subseteq E$ into the set $\{\gamma_x(A) | x \in A\}$ of its connected components; it is the coarsest partition whose all classes belong to C , and this partition increases with A : if $A \subseteq B$, then every connected component of A is included in a unique connected component of B ;
3. *Increasingness*: If C and C' are two connections on $\mathcal{P}(E)$, with $C \subseteq C'$, then the partition of A into its C' -components is coarser than that into its C -components;

Morphological Filtering,

Fig. 2 Left: Connection by partition: the connected component of A at point x is the union of the two pieces of particles of $A \cap D(x)$; right: connection by dilation the particles of each cluster generate a second connection

4. *Arcs*: The set A is connected for C if and only if for all $x, x' \in A$, one can find a component $X \in C$ that contains x and x' .

Connected Filters

In what follows, E is any space and $\mathcal{F}$ designates a lattice of functions $E \rightarrow \bar{R}$ (or $\bar{Z}$). We have already met a connected filter, since the datum of a connection C on E is equivalent to that of the connected point openings $\{\gamma_x | x \in E\}$. We shall extend a property of the latter by stating that an operator $\psi : \mathcal{F} \rightarrow \mathcal{F}$ is *connected* relatively to the connective criterion σ when for every $F \in \mathcal{F}$ and every $A \subseteq E$ it satisfies the implication:

$$\sigma[F, A] = 1 \Rightarrow \sigma[\psi(F), A] = 1. \quad (4)$$

In other words, the connection generated by the pair $(\sigma, \psi(F))$ contains that of (σ, F) . When, moreover, the operator ψ is a filter, one speaks of a *connected filter*. Since the partition of E into zones where $\psi(F)$ is homogeneous according to σ is coarser than that of E for (σ, F) , one proceeds from the second one to the first one by removing frontiers only. On the other hand, an operator that coarsens partitions is not necessarily connected. Some examples of connected filters are as follows:

1. E is provided with a connection C , and $\sigma(F, A) = 1$ for A connected and F constant over A . Every filter ψ that increases the flat connected zones, that is, those where F is constant, is connected. This corresponds to the usual meaning of the expression *connected filter* (Salember and Serra 1995).
2. E is still provided with the connection C , and $\mathcal{F}$ is the lattice of binary functions $E \rightarrow \{0, 1\}$. Since this lattice is isomorphic to $\mathcal{P}(E)$, we develop the example in the set-theoretical framework. The opening γ_x of the flat zones criterion applied to the set A gives simply the connected component of A that contains the point x . It is a connected filter, as well as, more generally, the opening $\gamma_M = \bigvee \{\gamma_x | x \in M\}$, called *of marker M* , where $\gamma_M(A)$, called *reconstruction opening*, is the union of connected components, or *grains* of A , that meet M .
3. Reconstruction openings and closings extend to numerical functions through flat operators (see an example in the article ► “Mathematical Morphology”). The set A (respectively, M) becomes the section of threshold t of the function F (respectively, of the marker function), one finds back criteria of the “flat zones” type. The alternating sequential filters of primitive connected openings and closings are themselves connected (see Fig. 1 above)

Connective Segmentation

In image processing, a numerical or multivalued function F is said to be segmented when its space of definition E has been partitioned into homogeneous regions, in the sense of some given criterion. The operation will be meaningful if the regions are as large as possible. But do all criteria lend themselves to such a maximum cut-out? Suppose for instance that we want to partition E into (connected or not) zones, where the numerical function f under study is Lipschitz of unity parameter. We run the risk of finding three disjoint zones A, B , and C such that the criterion will be satisfied on $A \cup B$ and on $A \cup C$, but not on $B \cup C$. In this case, there is no *largest region* containing the points of A and where the criterion is realized, so that the segmentation requires a non-deterministic choice between the partitions $\{A \cup B, C\}$ and $\{A \cup C, B\}$. This type of problem occurs typically in the “split and merge” approaches which have been used for more than 30 years in image segmentation.

How to sort out the criteria in order to be sure that they generate segmentation? First, we will make precise a few notions that are needed. Let E and T two arbitrary sets, and $\mathcal{F}$ a family of functions from $E \rightarrow T$. Then:

- A criterion $\sigma : \mathcal{F} \times \mathcal{P}(E) \rightarrow \{0, 1\}$ is a binary function such that for all $A \in \mathcal{P}(E)$ and all $F \in \mathcal{F}$ we have $\sigma[F, A] = 1$ when σ is satisfied by F on A and $\sigma[F, A] = 0$ when not. It is supposed that for all $F \in \mathcal{F}$ the criterion is always satisfied on the empty set: $\sigma[F, \emptyset] = 1$.
- A criterion σ is *connective* when:
 1. it is satisfied for the singletons:

$$\forall F \in \mathcal{F}, \forall x \in E, \sigma[F, \{x\}] = 1; \quad (5)$$

2. for all $F \in \mathcal{F}$ and all families $\{A_i | i \in I\}$ in $\mathcal{P}(E)$, we have:

$$\begin{aligned} \bigcap_{i \in I} A_i \neq \emptyset \text{ and } \bigwedge_{i \in I} \sigma[F, A_i] = 1 \\ \Rightarrow \sigma[F, \bigcup_{i \in I} A_i] = 1. \end{aligned} \quad (6)$$

- Finally, a criterion σ *segments* the functions of $\mathcal{F}$ when for all $F \in \mathcal{F}$, the family $\mathcal{D}(E, F, \sigma)$ of partitions of E whose all classes A satisfy $\sigma[F, A] = 1$, is non-empty and closed under *supremum* (including the empty one, $\mathcal{D}(E, F, \sigma)$ comprises the identity partition D_0). Then the partition $\bigvee \mathcal{D}(E, F, \sigma)$ defines the *segmentation of F according to σ* .

We saw that each connection on E partitioned every set $A \subseteq E$ into its maximum components. Therefore, if a criterion allows us to generate a connection associated to F , then we have good reason to think that it will segment the function. This is exactly what the following result states (Serra 2006):

Theorem of Segmentation *The following three statements are equivalent:*

1. *The criterion σ is connective*
2. *For each function $F \in \mathcal{F}$, the class of sets A where $\sigma[F, A] = 1$ is a connection*
3. *Criterion σ segments all functions of $\mathcal{F}$.*

Thus, a difficult problem (how to determine whether a class of partitions is closed under *supremum*?) comes down to the simpler question of checking whether a criterion is connective. Since this theorem turns out to be an alternative to the variational methods in segmentation, a short comparison is instructive.

1. In the connective approach, no differential operators intervene, such as Lagrange multipliers, for example. No assumption on the continuous or discrete nature of the space E is necessary: both E and T are arbitrary.
2. Moreover, not only the definition domain E of F is segmented, but even all the subsets of this domain. Therefore, if Y and Z are two masks in E , if $x \in Y \cap Z$, and if both segmentation classes $D_x(Y)$ and $D_x(Z)$ in x are included in $Y \cap Z$, then $D_x(Y) = D_x(Z)$ (in a traveling, the contours are preserved). The approaches based on global optimization of an integral in E are not able to obtain such a regional result.
3. The connective criteria form a complete lattice, where the *infimum* of the family $\{\sigma_i \mid i \in I\}$ is given by the Boolean minimum, what allows to parallelize the conditions. Note that if D_1 and D_2 are the segmentations associated with the two connective criteria σ_1 and σ_2 , then we have $\sigma_1 \leq \sigma_2$ if and only if $D_1 \leq D_2$, but the segmentation D relative to the $\inf \sigma = \sigma_1 \wedge \sigma_2$ satisfies only $D \subseteq D_1 \wedge D_2$. The petrographic example of Fig. 3 demonstrates an infimum of criteria.

Examples of Connective Segmentations

In what follows, we omit to repeat, for each criterion σ , that it is satisfied by the singletons and by the empty set (alternatively we could stop demanding that the singletons satisfy σ , and that would lead to a partially connective criterion (Ronse 2008)). Besides, the starting space E is supposed to be provided with an initial connection C_0 , which may intervene or not in the definition of the connective criterion under study, and the arrival space T is $\bar{R}$ or $\bar{Z}$.

The various connective segmentations can be classified into two categories, according to the presence, or the absence, of particular points, namely, the seeds. We begin with the second category, that we call the *simple* connective criteria.

Smooth Connection The criterion a for *smooth connection*, given by $\text{par } \sigma[F, A] = 1$ if and only if:

$$\forall x \in A, \exists a(x) > 0, \overset{\circ}{B}_{a(x)}(x) \subseteq A$$

$$\text{and } F \text{ is } k\text{-Lipschitz in } \overset{\circ}{B}_{a(x)}(x)$$

is obviously connective and induces the connection C_1 .

When C_0 is the arwise connection, the criterion $C = C_0 \cap C_1$ means that function F is k -Lipschitz along all paths included in the interior A° of A . In $\mathbb{Z}^2$, for example, where the smallest value of a is 1, it suffices, for segmenting, to erode the functions F and $-F$ by the cone $H(k, 1)$ whose base is the unit square (or hexagon), height is k , and summit the origin o , and then to take the intersection of the two sets where F (resp. $-F$) is equal to its eroded.

In the example of the micrograph of Fig. 3, one obtains for the smooth connection of slope 6 the white zones of Fig. 3(c), where the black ones indicate the isolated singletons. This connection differentiates the granular zones from those which are smoother, even when they both exhibit the same average gray value, as it often happens in electron microscopy.

Morphological Filtering, Fig. 3 From left to right: Electron micrograph of concrete, segmentation for a jump connection of value 12, segmentation by smooth connection of slope 6, infimum of the jump and smooth criteria

Connections by Clustering on Seeds Many segmentation processes work by binding together points of the space around an initial family $G_0 \subseteq E$ of seeds, which may possibly move, or whose number may vary when the process progresses during several iterations. All these processes satisfy the following property:

Theorem of Seeds *Given a function $F \in \mathcal{F}$, an initial family G_0 of seeds, and an aggregation process that yields the final seeds G , the criterion σ obtained by:*

$$\sigma[F, A] = 1$$

if all points of A are allocated to a same final seed $g \in G$, and $\sigma[F, A] = 0$ otherwise, is connective.

Watershed lines: We now interpret the numerical function F as a relief in R^n or Z^n . All points of the relief whose deepest descent line ends to a same minimum form an arcwise connected catchment basin, and the singletons which do not belong to any catchment basin define the watershed (Lantuéjoul and Beucher 1981). There exist several method to obtain a watershed. One can notice that for binary images, the watershed is nothing but the SKIZ of Lantuejoul, or skeleton by zones of influence. It extends to numerical functions by level set approach, the portion of watershed of level i being the geodesic SKIZ of level i inside level $i - 1$ (Meyer and Beucher 1990; Najman et al. 2012) (see also [Serra 1982] in the article ► “Mathematical Morphology”). Alternatively, one can determine the steepest descents of the points towards minima (Cousty et al. 2009; Bertrand 2005). The reference [Najman and Talbot 2010] in the article ► “Mathematical Morphology” comprises several chapters on the subject.

Whatever the exact way, the watershed line has been introduced, the theorem of seeds shows that the involved criterion is connective. Now, among the singleton components we find of course the crest line, but also all points x of the intermediate flat zones, like stairs, stuck between an upstream and a downstream, and where F is constant on an

open set surrounding x . We then take for second connective criterion that “each point x of an intermediate flat zone goes to the same catchment basin as the point of the downstream frontier closest to x .” This criterion is applied to the set of singletons; by repeating the process as many times as needed for going up from stair to stair, one finally reduces the singleton zones to the true crest lines.

Remark that the watershed of function F gives the zones of influence of the minima of F , as can be shown in Fig. 4 (first two left images), and not the contours of the objects. The latter appear as the watershed lines of the $|\text{gradient}(F)|$ image, as one can see in Fig. 4 (last two left images). Moreover, for the sake of robustness, the gradient image is stamped here by the desired minima, which are both minima and watershed lines of F .

Jump connection: It is a kind of alternative to watershed, which often leads to excellent segmentation. The jump connection works by aggregating seeds, each one being a connected basin of given height around a minimum. The space is supposed to be equipped with an initial connection C_0 , and a jump value $k > 0$ is fixed. Around the supports M of the minima, we build the largest connected sets $S_1(M)$ where the level goes up from 0 to $k - 1$.

By binding the $S_1(M)$ one obtains the components associated to the first application of the jump criterion. A second application of the criterion, this time on the residual, gives new components $S_2(M)$, etc. until nk exceeds the dynamic of values of the function (Fig. 5). The family $\{S_i(M)\}$ is the set of classes of the final jump partition. Alternatively, one can jump up from the minima, and down from maxima, in a symmetrical manner (Serra 2006).

Returning to the micrograph of Fig. 3, we observe that the smooth connection and the jump connection taken alone are not excellent, but that the infimum of the two criteria suppresses the noise, and gives a satisfactory result.

Compound Segmentation

Instead of parallelizing criteria, one can also take them into account successively, and segment differently various regions

Morphological Filtering, Fig. 4 Watershed of an electrophoresis and of its derivative

Morphological Filtering,
Fig. 5 The first two steps of a
 jump connection

Morphological Filtering, Fig. 6 From left to right: initial photo, segmentation of the face (color criterion), marker for the bust, final segmented silhouette. (By courtesy of C. Gomila)

of an image. For this purpose, one relaxes the first axiom of connective criteria, namely, relation (5). This condition aims at guaranteeing that every point of the space belongs to a class of the performed segmentation. By breaking away from relation, one thus renounce the covering of a set by the classes of a partition or by its connected components. This approach, formalized by C. Ronse (2008), is based on partial connections and leads to more flexible processing.

In the example of Fig. 6, one tries to segment silhouettes of the person in Fig. 6 (left). A first partial segmentation, based on the hue of the skin and the hair, leads to the head contour. A second segmentation that deals only with the complement of the head, extracts next the shoulder from the marker formed by three superposed rectangles (minus the already segmented points). The union of the two segmentations leads to the mask in Fig. 6 (right).

Hierarchies of Partitions

From now on we concentrate upon the morphological filtering and segmentation defined on finite hierarchies of partitions in R^2 or Z^2 , for whatever origin. They can be due to anterior connected filters, or not. Figure 7 (left), for example,

represents administrative divisions around the city of Paris, which generate a hierarchy of four partitions according to some parameter. The hierarchies of same base, same top, and same number of levels form a complete lattice for the product ordering of their partition levels.

A hierarchy can be summarized in two ways, depending on whether we focus on the edges or on the classes. Both ways are equivalent but serve differently. Firstly, one can weight the edges by the level when they disappear. That condenses the hierarchy into a unique map of the so-called *saliencies*. The saliency maps lend themselves to morphological filtering on hierarchies. For example, the operation which suppresses all edges of saliency $\leq \lambda$, or shorter than μ , and leaves unchanged the others, is a closing and it generates an anti-granuometry as λ increases (see Ch.9 in the reference [Najman and Talbot 2010] of the article ► “Mathematical Morphology”).

Alternatively one can replace the hierarchy by its *dendrogram*, as depicted in Fig. 7 (right), i.e., by a tree whose levels are those of the hierarchy. The top level is called the root and the lowest level the leaves. The classes, or nodes, are indicated by small discs and their ordering is described by arrows. The parameters associated with the classes are usually written

Morphological Filtering, Fig. 7 Displays of a hierarchy

in the small discs. The dendrogram highlights the “sons” of each class S , i.e., the partial partition just below S . The relation between classes and sons directly intervenes when looking for minimal cuts.

Formally speaking, a partition D is a map $E \rightarrow \mathcal{P}(E) : x \mapsto D(x)$ that satisfies the following two conditions:

- for all $x \in E$, $x \in D(x)$;
- for all $x, y \in E$, $D(x) \cap D(y) \neq \emptyset \Rightarrow D(x) = D(y)$.

$D(x)$ is called the *class* of the partition in x . Partition D is *finer* than partition D' when each class of D is included in a class of D' . One writes $D \leq D'$. This relationship defines the *refinement* ordering, which provide partitions with the structure of a complete lattice (see article ► “[Mathematical Morphology](#)”). A hierarchy is an ordered sequence of partitions (e.g., Fig. 7 bottom). In the following, we start from a unique hierarchy H and consider the family $\mathcal{H}$ of all the hierarchies whose classes are taken among those of H . Similarly, we name *cut through hierarchy* H any partition D whose all classes are taken among the classes of the hierarchy and we denote by $\mathcal{D}$ the set of all cuts of H . Finally, when the partitioning is restricted to a class S of the hierarchy H , one speaks of *partial partition* of support, or nod, S .

Optimal Cuts

Suppose we want to summarize the hierarchy into a significant partition. The information conveyed by the parameters on the classes may be pertinent for some classes at a certain level and for others at another level. In order to express this

pertinence, one classically associates an energy ω with each partial partition of H . Three questions arise here, namely:

1. Most of the segmentations involve several features (color, shape, size, etc.). How to combine them in unique energy?
2. How to generate, from the set of all partial partitions, a partition that minimizes ω , and which can be determined easily?
3. When one energy ω depends on an integer λ , i.e., $\omega = \omega_\lambda$ how to generate a sequence of optimal partitions that increase with λ , which therefore should form an optimal hierarchy?

These questions have been taken up by several authors, over many years, and by various methods. Morphological approach unifies them and allows to go further. We will successively answer the three above questions.

Dynamic Programming

The most popular energies ω for hierarchical partitions derive from that of Mumford and Shah (Arbelaez et al. 2011; Guigues et al. 2006; Salembier and Garrido 2000). It is defined in each class as the sum of a fidelity term (e.g., the variance of the values) and a boundary regularization term (e.g., the length of the edges). The energy of a partial partition is the sum of those of its classes. The optimization turns out to be a trade-off between fidelity and regularization.

In 1984, L. Breiman (Breiman et al. 1984) introduced a dynamic programming method to determine the cut of minimum energy in a hierarchy. The hierarchy is spanned only

Morphological Filtering,

Fig. 8 Breiman's minimal cut over the hierarchy: the energy ω at node S is compared to the sum of the energies of its sons T_S . When $\omega(S) \leq \sum \omega(T_S)$ one keeps S , when not, one replaces S by its sons

once, from the leaves to the root. The energy of each node S is compared to the sum of the energies of its children, and one keeps the partial partition which has the least energy. In case of equality one keeps S . Fig. 8 depicts a dendrogram with the energies of the classes and the minimal cut, i.e., the partition with the least total energy.

However, one can wonder whether additivity is the very underlying cause of the simplifications via a unique spanning, since Soille's constrained connectivity (Soille 2008), where the addition is replaced by the supremum, satisfies similar properties. Finally, one finds in literature a third type of energy, which holds on nodes only, and no longer on partial partitions. It appears in labeling methods (Arbelaez et al. 2011), and again, it yields optimal cuts. Is there a common denominator to all these approaches, more comprehensive than just additivity, and which explains why they always lead to unique optima?

Energetic Lattices

Consider a given hierarchy H , and the family $\mathcal{D}$ of all its cuts. An energy ω is assigned to all partial partitions of H whose support S is a class of H . Let $D_1, D_2 \in \mathcal{D}$, be two cuts. At point x , either the class $D_1(x)$ is the node $S_1(x)$ support of a partial partition $D_2(x)$ of D_2 , or we have the inverse. We then say that cut D_1 is ω -smaller than D_2 when

$$\omega[D_1(x)] = \omega[D_2(x)] \text{ and } D_2(x) = S_1(x).$$

These two conditions define an order relation over the set of the cuts $\mathcal{D}$ of hierarchy H , which in turn induces a complete lattice on the cuts $\mathcal{D}$. Both ordering and lattice are said *energetic* (Kiran and Serra 2014). The structure of the cuts as an energetic lattice guarantees us that there is one and only one minimal cut, which is not useless (see Fig. 1 in (Kiran and Serra 2015)).

 h -Increasingness and Partition Closing

The common property of all energies which make use of dynamic programming is that they all are h -increasing

(Kiran and Serra 2014). Let D_1 and D_2 be two partial partitions of the same support S , and D_0 a partial partition of support S_0 disjoint of S . An energy ω over the partial partitions is said to be h -increasing when:

$$\omega(D_1) \leq \omega(D_2) \Rightarrow \omega(D_1 \sqcup D_0) \leq \omega(D_2 \sqcup D_0)$$

where the symbol " $\sqcup$ " stands for the concatenation of two partial partitions.

When the energy ω is h -increasing, and only then, each step of the dynamic programming is an increasing and extensive operation on the family $\mathcal{H}$ of hierarchies, so that at the end, when the root is reached, we obtain the *closing* of H w.r.t. energy ω . This closing is a hierarchy whose all levels are identical, and equal to the unique minimal cut.

h -increasing energies include, of course, the classical additive energies, but also the composition laws by infimum, harmonic sum, number of classes, quadratic sum, and supremum, among others.

Families of Minimal Cuts

An energy ω_δ over the partial partitions is said *inf-modular* when for each partial partition D of support S we have

$$\omega_\delta(\{S\}) \leq \wedge \omega_\delta[D(x), x \in S].$$

The Lagrange formalism proposes a convenient way to order a family of minimal cuts (Guigues et al. 2006; Soille 2008). Introduce a scalar Lagrange family of energies by $\{\omega(\lambda) = \omega_\varphi + \lambda \omega_\delta, \lambda > 0\}$ where $\omega(\lambda)$, ω_φ , and ω_δ are h -increasing, and further ω_δ is inf-modular.

These energies are defined over partial partitions, and we suppose $\lambda > 0$. Given hierarchy H , the three energies $\omega(\lambda)$, ω_φ , and ω_δ induces the three energetic lattices over the set $\mathcal{D}$ of all cuts of hierarchy H , namely, $\mathcal{D}_\lambda$, $\mathcal{D}_\varphi$, $\mathcal{D}_\delta$. Just as for the constrained minimization for functions, the energy $\omega(\lambda)$ stands for the Lagrangian of objective term ω_φ and constraint term ω_δ . The constrained Lagrangian minimization results then in the minimal cut of H w.r.t. energy $\omega(\lambda)$. This minimal

Morphological Filtering, Fig. 9 Left: initial view; right: minimal cut for an additive energy. (By courtesy of L. Guigues)

Morphological Filtering, Fig. 10 Two cuts of the minimal hierarchy

cut increases with λ for the refinement order, so that it produces a new hierarchy H^* (Kiran and Serra 2015). Remark that one does not change the H^* by iterating the process.

Figs. 9 and 10 give an example of the optimal hierarchy H^* . It depicts the evolution of the optimal cuts when ω_φ and ω_δ are the variance of the values and the length of the edges in a partial partition, respectively. The parameter λ increases when going from left to right, and the minimal cut of Fig. 9 (right) corresponds to a transitional λ . We see that for the greatest λ , the fields are well rendered, but the region of the village, which has a high length of edges, is swept out. Here a better technique would probably be the Ronse compound segmentation (Ronse 2008), as demonstrated in Figs. 6 and 10.

Summary

The contribution of Morphological Filtering to geosciences and more generally to image processing can be contemplated

from the two points of view of theory and practice. Several notions used in qualitative description receive a precise meaning in mathematical morphology, owing to adapted axioms. Morphological filtering: turns out to be a sort of trade-off between its two axioms of increasingness, which simplifies the structures under study, and idempotence, which blocks the simplification. The axioms of a connection directly apply to the objects which are connected in the usual sense, but also to those which may seem disconnected at first glance, like the dotted lines of a trajectory. When a connection is added to the filters, then they come to segmentation methods. They extract, from numerical functions, partitions of the space into regions where these functions are homogeneous in the sense of a given connective criterion. In image processing this process is called a segmentation. When it depends on a positive parameter, segmentation results in a sequence of increasing partitions called a hierarchy. Then a closing filter on the hierarchy allows us to extract its “best” segmentation.

Some of the above examples belong to petrography or to remote sensing, thus come within the domain of geosciences.

But the others, like district grouping, or zones of influence of spots, can easily be transposed to geosciences questions. Morphological Filtering intervenes, indeed, at all scales and includes hydrology, generation of maps, fractal landscape description, etc. (Sagar 2013).

Morphological Opening

Sravan Danda¹, Aditya Challa¹ and B. S. Daya Sagar²

¹Computer Science and Information Systems, APPCAIR, Birla Institute of Technology and Science, Pilani, Goa, India

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Morphological opening is one of the basic operators from the field of Mathematical Morphology (MM). It is also one of the simplest morphological filters used for constructing more complex filters. This operator is dual to Morphological Closing. In general, morphological opening is defined as a composition of an erosion followed by a dilation. So, in the case of discrete binary images, if X denotes the binary image and B denotes the structuring element, morphological opening is defined as

$$\gamma_B(X) = \delta_B(\varepsilon_B(X)) = (X \ominus B) \oplus B \quad (1)$$

This definition can be reduced to

$$\gamma_B(X) = \cup\{B_x | B_x \subseteq X\} \quad (2)$$

Equivalently, in the case of gray-scale images, if f denotes the gray-scale image and g denotes the structuring element, opening is defined as

$$\gamma_g(f) = \delta_g(\varepsilon_g(f)) \quad (3)$$

Illustrations

Morphological opening is one of the basic operators from the field of Mathematical Morphology. Its definition can be traced to fundamental works by Jean Serra (1983, 1988) and Georges Matheron (1975). In general, morphological opening is defined as an erosion operator composed with a dilation operator. In this entry, we illustrate the opening operator using binary images, and discuss various properties. We also discuss the more general algebraic openings.

In simple words, (2) considers the union of all the translations of the structuring element which fits into the original set. This is illustrated in Fig. 1. Here, the structuring element is taken to be a simple disk denoted by a dashed line in Fig. 1. All the points that do not fit within the structuring element are removed. In Fig. 1, this corresponds to the spiked projection of the larger disk.

Although not discussed here, similar intuition follows in gray-scale images as well.

Morphological Opening, Fig. 1 Illustration of Morphological Opening. The shaded area refers to the set obtained by opening

Some Important Properties

The properties of the opening operator are explained using the binary images. However, these extend to the gray-scale images as well (see Dougherty and Lotufo (2003)). Firstly, morphological opening is an *increasing operator*,

$$X \subseteq Y \Rightarrow \gamma_B(X) \subseteq \gamma_B(Y) \quad (4)$$

Moreover it is also an *anti-extensive operator*

$$X \supseteq \gamma_B(X) \quad (5)$$

Also, the opening operator is idempotent

$$\gamma_B(\gamma_B(X)) = \gamma_B(X) \quad (6)$$

Algebraic Openings

Morphological openings are a subset of a wider class of operators known as *Algebraic Openings*. An algebraic opening is defined as any operator on the lattice which is: (a) increasing (b) anti-extensive, and (c) idempotent. It is easy to see that morphological opening is a specific example of algebraic openings.

Morphological Opening, Fig. 2 Application of Morphological Opening. Using the white top-hat transform one can remove the illumination effects. https://scikit-image.org/docs/dev/auto_examples/color_

[exposure/plot_regional_maxima.html#sphxglr-download-auto-examples-color-exposure-plot-regional-maxima-py](https://scikit-image.org/docs/dev/auto_examples/color_exposure/plot_regional_maxima.html#sphxglr-download-auto-examples-color-exposure-plot-regional-maxima-py). Copyright: 2009–2022 the scikit-image team. License: BSD-3-Clause

An example of algebraic opening, which is not a morphological opening, is *Area Opening* – remove all connected components of the image that has an area lesser than the parameter λ . (Recall that in a binary image, two adjacent pixels x, y are said to be connected if they have the same value. A path between two pixels x, y is a sequence of pixels $x = x_0, x_1, \dots, x_k = y$ such that x_i and x_{i+1} is connected. A subset is said to be connected if for any two pixels in the subset there exists a path between them. A connected component is a maximal subset which is connected.)

In Matheron (1975) it is shown that any algebraic opening can be defined as a supremum of morphological opening.

Application to Filtering

Recall that, in the context of mathematical morphology, an operator which is increasing and idempotent is referred to as a *filter*. As stated earlier, morphological opening is one of the simplest filters based on which complex filtering operators such as top-hat transforms, granulometries, and alternating sequential filters are constructed. Here we discuss the example of *White top-hat* transform which is defined as

$$\text{WTH}(f) = f - \gamma(f) \quad (7)$$

or simply $\text{WTH} = \mathbf{I} - \gamma$ where $\mathbf{I}$ is the identity operator. The effect of this operator is illustrated in Fig. 2. A simple thresholding of the original image results in dark patches. This is due to the bad illumination of the image. The dark patches can be removed by opening with a large structuring element and subtracting the result from the original image, as White-top-hat transform. By thresholding the filtered image, the illumination effects can be seen filtered out.

Summary

In this entry, morphological opening is defined for binary and gray-scale images. The practical utility of morphological opening is then illustrated using a fictitious binary image. The main properties of morphological opening, namely, increasing, anti-extensiveness and idempotence are then mentioned. A generalized notion of morphological opening, i.e., algebraic opening is defined. The entry concludes by describing the construction of more complex filter: White-top-hat transforms using morphological opening, along with illustrations on real images.

Morphological Pruning

Sin Liang Lim¹ and B. S. Daya Sagar²

¹Faculty of Engineering, Multimedia University, Cyberjaya, Selangor, Malaysia

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

In digital image processing, skeletonization and thinning algorithms are procedures that tend to leave parasitic components, or “spurs” behind. As a result, pruning is a technique that could be adopted as an essential procedure to eliminate these unwanted spurs. The spurs, in this case, refer to unwanted branches of line which should be removed since, by removing them, the overall shape of the line is not affected. These parasitic components are the undesirable result generated from edge-detection algorithms (e.g., character recognition, car plate detection) or digitization. Very often, these spurs can be treated as “noise” and thus they should be cleaned-up before proceeding to the subsequent procedure.

Introduction

Pruning is an important post-processing operator that complements skeletonization and thinning algorithms because these operations tend to leave spurs that need to be eliminated (Gonzalez and Woods 2008; Shaked and Bruckstein 1998). Skeletons are concise descriptors of objects in images (Duan et al. 2008; Maragos and Schafer 1986). Skeletonization, on

the other hand, often provides a compact yet effective representation of two-dimensional and three-dimensional objects. Skeletonization is commonly applied in many low-level and high-level image-processing applications which include object representation, tracking, recognition, and compression. Furthermore, skeletonization also facilitates efficient description of geometry, topology, scale, and other local properties related to the object (Saha et al. 2017; Baja 2006). Particularly, skeletonization is used in automated character recognition including handwritten characters recognition to extract the skeleton of each character (Gonzalez and Woods 2008). However, skeletonization will often result in not only the skeleton but also the parasitic components, or “spurs.” Spurs are created as a result of erosion due to the non-uniformities in the strokes that are possessed by the characters.

Methodology

In Gonzalez and Woods (2008), a morphological-based pruning framework was developed by assuming that the length of a parasitic component does not exceed a certain number of points. In other words, the standard pruning algorithm will eliminate all branches shorter than a specific number of pixels. For example, if a parasitic branch is shorter than three points and the thinning algorithm is repeated for three times, then the parasitic branch will be removed. The framework comprises four steps: (i) thinning, (ii) finding end points, (iii) dilating end points, and (iv) union. It is highlighted that step (ii) is performed to ensure that the main branch of each line are preserved and not shortened by the procedure. The algorithms and the example in Fig. 1 below are adapted with permission from Digital Image Processing, fourth Edition by Gonzales and Woods, Pearson 2018.

Step 1: Thinning

$$X_1 = A \otimes \{B\} \quad (1)$$

Thinning of set A with a sequence of structuring element $\{B\}$ is performed, as shown in Eq. 1.

As an example, Fig. 1a shows the skeleton of a hand-printed letter “a” and it is denoted as set A . It is observed that the leftmost part of the character (three pixels in vertical) represents the “spur” which should be removed. This leads us to assume that any branch with three or less pixels should be removed.

Figure 1b represents the ordered list of 8 structuring elements which is rotated 90° and each of which contains two pixels. The “ $\times$ ” symbol denotes a “don’t care” condition. In order to remove any branch with n or less pixels, Step 1 has to

be repeated for n times. In this case, since the spur is determined to be three pixels, thus Step 1 is repeated three times to generate set X_1 in Fig. 1c.

Step 2: Find End Points

$$X_2 = \bigcup_{k=1}^8 (X_1 \ominus B^k) \quad (2)$$

In this step, a set X_2 containing all end points in X_1 is constructed. In Eq. 2, B^k denotes end-point detectors which are used to determine the end points in X_1 using the hit-and-miss operation of B^k with X_1 . End points are defined as the points where the origin of the structuring elements are satisfied. Fig. 1d shows the resultant X_2 which consists of two end points.

Step 3: Dilate End Points

$$X_3 = (X_2 \oplus H) \cap A \quad (3)$$

The next step is to perform dilation of the end points as conditioned on A , as given in Eq.3. In particular, the end points is dilated using a 3×3 matrix (H) which contains all 1’s and intersects with A . This step is executed n times in all directions for each endpoint.

In this example, as no new spurs are created by inspection, the end points are dilated three times with reference to A as delimiter. This is the same number as the thinning process in Step 1. Fig. 1e represents the resultant X_3 .

Step 4: Union of X_1 and X_3

$$X_4 = X_1 \cup X_3 \quad (4)$$

The purpose of the last step is to restore the character to its original form but with the spurs removed. In essence, the union of X_1 and X_3 will produce the final pruned image X_4 , as shown in Fig. 1f.

Case Studies

For simple illustration, the ASTER Global Digital Elevation Model (ASTER GDEM) of the mountainous area in Cameron Highlands, Pahang in Malaysia is taken as the study area for extracting the pruned image. With elevation up to 1600 meters above sea level, the study area covers the tea plantation, vegetable farm, and various other agricultural activities. The study area encompasses 400 km^2 with coordinates of $4^\circ 22' 57'' \text{ N}$ to $4^\circ 33' 50'' \text{ N}$ and $101^\circ 22' 4'' \text{ E}$ to $101^\circ 32' 50'' \text{ E}$ (Lim et al. 2016; Kalimuthu et al. 2016).

Morphological Pruning, Fig. 1 (a) Set A , (b) sequence of structuring elements B used for detecting end points, (c) X_1 - after three cycles of thinning, (d) X_2 - end points detected, (e) X_3 - dilation of X_2 based on (a), (f) X_4 - Final pruned image of (a)

Morphological Pruning, Fig. 2 (a) DEM of the study area in Cameron Highlands, Malaysia, (b) binary image of (a), (c) skeleton image of (b), and (d) pruned image of (c)

Figure 2a shows the DEM of the study region in Cameron Highlands with resolution of 257×258 pixels. Figure 2b is the resultant image after binarization is performed on Fig. 2a. Figure 2c shows the skeleton image of Fig. 2b. It is observed that there are some parasitic branches (spurs) that appear in the end points of the objects. Hence, after pruning is applied, Fig. 2d shows the final pruned image of Fig. 2a where most of the spurs have significantly been removed resulting in a cleaner skeleton image.

Morphological pruning has been applied in many applications related to geoscience. For example, in Tay et al. (2006), the traveltime channel networks were pruned downward from the tips of the branches to the stationary outlet. This mimics realistic phenomenon such as burning of fire from all the extremities of river source, and propagate progressively toward the outlet. The corresponding convex hulls of the traveltime pruned networks were also computed, which leads to the derivation of convexity measure. Based on the

Morphological Pruning, Fig. 3 (a) An example of (nonconvex set) channel network where the source point is represented as a round dot at the bottom of the tree, (b) convex hull of (a), (c) Traveltime pruned

network until it reaches the outlet, (d) union of corresponding convex hulls of pruned networks in (c). This figure is adopted from (Tay et al. 2006)

convexity measures obtained, new power law relations could be further derived to characterize the scaling structure of the networks. The proposed methodology has been explained with the use of a simple tree-like non convex set, shown in Fig. 3a. Its corresponding convex hull is as shown in Fig. 3b.

The traveltime network of Fig 3a are pruned recursively towards the outlet and color-coded in Fig. 3c, while Fig. 3d illustrates the convex hulls of the traveltime channel network. Furthermore, the framework has been applied on seven sub-basins of Cameron Highlands, Malaysia and the convexity

measures acquired from the dynamically shrinking traveltime basins which move toward their outlets offers geophysicists and geomorphologists a better visualization and understanding of the channelization process.

Summary or Conclusions

Morphological pruning is a useful technique for post-processing to eliminate unwanted parasitic components which appear following skeletonization and thinning operations. We have demonstrated the use of morphological pruning to eliminate unwanted parasitic components in the digital elevation model (DEM). From the results, it is obvious that morphological pruning is able to remove the unwanted spurs and helps to generate a cleaner output with significantly lesser noise. This framework can be applied to extract the ridge of the mountains or to determine the contour lines of drainage basins from the DEMs. Furthermore, it is proven that pruning can be adopted to applications related to geoscience which helps in deriving statistically significant metrics.

Definition

Morphometry is usually reckoned as the quantitative analysis of solid earth surface morphology. It is mainly focused on the analysis of topography and bathymetry; however, its related concepts and methods can be applied to the analysis of any surface, being it natural (e.g., planetary geomorphology) or anthropic (e.g., surface metrology), and at any spatial scale. The morphometric analysis is most efficiently conducted by means of geocomputational tools applied to digital representations (1D, 2D, etc.) of earth surface. The computational algorithms are implemented both in standalone specialized software for terrain analysis as well as additional tools in Geographical Information Systems (GIS). The morphometric analysis can be conducted also in the field by means of field equipment, e.g., for the characterization of local characteristics and for validation purposes. In a broader sense, morphometry also includes the quantitative spatial analysis of morphometric features, such as the drainage network and structural lineaments; in this context, the analysis can be conducted with geocomputational tools applied to remote sensing imagery.

Introduction

Topography is one of the main factors controlling processes taking place in the near-surface layer of the planet and it is expression of multiple geomorphic processes and factors. Accordingly, it is not surprising that the qualitative and quantitative study of surface morphology has a long record of research in the geosciences. For example, the work of Strahler on hypsometry (see ► [“Hypsometry”](#)) is emblematic of the use of quantitative methods for the description of surface morphology. Moreover, the heterogeneity and complexity of topographic surfaces and features have always attracted scientists; in this perspective, the development of fractal theory

(Mandelbrot 1967) is emblematic. Before the 1990s, topographic maps were the main source of quantitative information on topography. These maps were analyzed using geomorphometric techniques to calculate manually morphometric variables and produce morphometric maps. In the mid-1950s, a new research field – digital terrain modeling – emerged in photogrammetry. Within its framework, digital elevation models (DEMs), two-dimensional discrete functions of elevation, became the main source of information on topography. DEMs were used to calculate digital terrain models (DTMs), two-dimensional discrete functions of morphometric variables. Initially, digital terrain modeling was mainly applied to produce raised-relief maps using computer-controlled milling machines, and to design highways and railways. However, digital terrain modelling became widely applicable many years later, thanks to technological innovations in computing and topographic data collection.

Relevant developments in the physical and mathematical theory of the topographic surface in the gravity field accompanied the technological innovations. As a result, geomorphometry evolved into the science of quantitative modeling and analysis of the topographic surface and of the study of its relationships with the other natural and artificial components of geosystems. Currently, geomorphometry is widely adopted to solve various multiscale problems of geomorphology, hydrology, remote sensing, soil science, geology, geophysics, geobotany, glaciology, oceanology, climatology, planetology, and other disciplines (e.g., Moore et al. 1991; Pike 2000; Hengl and Reuter 2009; Florinsky 2016; Wilson 2018). Geomorphometric analysis has deep interconnections with many geocomputational, statistical, and mathematical approaches; these include geostatistics, fractal analysis, spectral methods (e.g., wavelets, Fourier analysis, etc.), mathematical morphology (Sagar 2013), and many others. Moreover, considering the raster representation of elevation, morphometry has strong methodological interconnections with image analysis and pattern recognition algorithms, with various examples of applications of advanced pattern recognition approaches such as the Local Binary Pattern or the classical gray level co-occurrence matrix (e.g., Haralick et al. 1973). In this context, the links between topographic surface roughness (or, as synonym, surface texture) and image texture analysis are evident (Haralick et al. 1973; Trevisani and Rocca 2015).

The current popularity of morphometry is strongly related to recent technological innovations in multiple fields, including techniques for the derivation of digital terrain models, computational power, and software development. Cloud storing services and parallel computing will play a key role in the next future, given the increasing need of computational resources for storing and analyzing digital elevation data. In

fact, the quantity of topographic-related data is continuously increasing for multiple reasons. First, new sensing technologies, e.g., LiDAR (Light Detection and Ranging) and SAR (Synthetic Aperture Radar), permit the efficient collection of topographic data for wide areas and at high resolution. Second, the increase in the geosphere-anthroposphere interactions and the need to deal with multiple geoenvironmental issues (e.g., natural hazards) require an accurate, detailed, and, often, multi-temporal knowledge of surface morphology. Third, the morphometric analysis can be conducted by means of a variety of algorithms, permitting to derive a wide set of morphometric variables and local statistical indices (e.g., Pike 2000; Florinsky 2017); moreover, the various morphometric indices can be computed at multiple scales.

Geomorphometric methods provide a multiscale quantitative description of solid-earth surface morphology by means of multiple derivatives and local statistical indices. These can be used directly for a visual analysis and a description of landscape, for comparing the morphometric characteristics of different study sites and for studying the connections between morphology and geomorphic processes and factors. Some morphometric indices can be also used as parameters in physical-based computational models; for example, local roughness indices can be used as impedance factor in surface-flow models. Often, the calculated geomorphometric features are further processed by means of supervised (e.g., landslide susceptibility models, soil properties mapping, etc.) or unsupervised learning approaches (e.g., landscape classification). In this context new, approaches based on machine learning are becoming increasingly popular in geomorphometric analysis.

Morphometry is inherently related to the field of remote sensing. First, frequently the digital elevation models are derived by means of remote sensing technologies, using active (e.g., LiDAR, SAR, etc.) or passive (e.g., imagery) sensors, mounted on a wide set of platforms (terrestrial, satellite, aerial, etc.). Second, many of the techniques adopted to analyze digital elevation models can be applied to the analysis of remote sensing imagery and vice versa. Third, relevant morphological features (e.g., structural lineaments) that can be analyzed quantitatively can be derived from remote sensing imagery. Fourth, in many applications (e.g., for studying soil properties, for mapping landslide susceptibility, or for ecological considerations), the quantitative analysis can be performed by means of an integrated use of morphometric derivatives and remote sensing-derived variables. Fifth, digital elevation models and local morphometric characteristics (e.g., slope, aspect, roughness, etc.) are important factors for the processing of remote sensing products (e.g., orthorectification of imagery, post-processing of SAR products, etc.).

Morphometrics

The digital representation of surface morphology is crucial for modern geomorphometry. The most popular and easy implementation is based on a 2.5 D representation of topography by means of a raster coding: i.e., the topography is represented by a single band image, in which the value of the pixel is the elevation. According to this representation, topographic surface is uniquely defined by a continuous, single-valued bivariate function

$$z = f(x, y), \quad (1)$$

where z is elevation, and x and y are the Cartesian coordinates. This means that caves, grottos, and similar landforms are excluded. However, alternative approaches for digital representation of topography can be adopted, including, for example, true 3D representations (i.e., caves can be represented), 3D digital globes, triangulated irregular networks, etc.

Even if there is not a consensus, many researchers differentiate morphometrics (i.e., indices describing some aspects of surface morphology) between morphometric variables and local statistical indices. Morphometric variables (Fig. 1) generally imply specific mathematical requirements for the representation of topographic surface (e.g., differentiability, see Florinsky 2017) and are defined through their relation with the gravity field (see section “[Local Morphometric Variables](#)” difference between flow and form attributes).

Local statistical indices do not require particular mathematical properties in the topographic surface data to be analyzed and are not necessarily related to the gravity field. For example, an important set of local statistical indices is adopted to describe surface roughness (or its synonym “surface texture”), a fundamental property of surface morphology. Surface roughness is a complex and multiscale characteristic that cannot be described by a single mathematical index (Fig. 2). In this regard, there is a quite ample literature on the use and development of surface texture indices (e.g., Haralick et al. 1973; Grohmann et al. 2011; Trevisani and Rocca 2015).

Given that morphometric variables represent the core of geomorphometry, we furnish a basic review of the fundamental ones. A morphometric (or topographic) variable (or attribute) is a single-valued bivariate function describing properties of the topographic surface. Here, we review fundamental topographic variables associated with the theory of the topographic surface and the concept of general geomorphometry, which is defined as “the measurement and analysis of those characteristics of landform which are applicable to any continuous rough surface. ... General geomorphometry as a whole provides a basis for the quantitative comparison ... of qualitatively different landscapes ...” (Evans 1972, p. 18). There are several classifications

of morphometric variables based on their intrinsic (mathematical) properties (Shary et al. 2002; Florinsky 2016). Here, the classification of Florinsky (2017) is adopted.

Morphometric variables can be divided into four main classes: (1) local variables; (2) nonlocal variables; (3) two-field specific variables; and (4) combined variables. The terms “local” and “nonlocal” are used regardless of the study scale or model resolution. They are associated with the mathematical sense of a variable (c.f. the definitions of a local and a nonlocal variable). Being a morphometric variable, elevation does not belong to any class listed, but all topographic attributes are derived from DEMs.

Local Morphometric Variables

A local morphometric variable is a single-valued bivariate function describing the geometry of the topographic surface in the vicinity of a given point of the surface, along directions determined by one of the two pairs of mutually perpendicular normal sections (Fig. 3).

A normal section is a curve formed by the intersection of a surface with a plane containing the normal to the surface at a given point. At each point of the topographic surface, an infinite number of normal sections can be constructed, but only two pairs of them are important for geomorphometry.

The first pair of mutually perpendicular normal sections includes two principal sections (Fig. 3a) well known from differential geometry. These are normal sections with extreme – maximal and minimal – bending at a given point of the surface.

The second pair of mutually perpendicular includes two normal sections (Fig. 3b) dictated by gravity. One of these two sections includes the gravitational acceleration vector and has a common tangent line with a slope line at a given point of the topographic surface. The other section is perpendicular to the first one and tangential to a contour line at a given point of the topographic surface.

Local variables are divided into two types – form and flow attributes – which are related to the two pairs of normal sections (Shary et al. 2002).

Form attributes are associated with two principal sections. These attributes are gravity field invariants. This means that they do not depend on the direction of the gravitational acceleration vector. Among these are minimal curvature ($k_{\min}$), maximal curvature ($k_{\max}$), mean curvature (H), the Gaussian curvature (K), unsphericity curvature (M), Laplacian (∇^2), shape index (IS), curvedness (C), and some others.

Flow attributes are associated with two sections dictated by gravity. These attributes are gravity field-specific variables. Among these are slope (G), aspect (A), northwardness (AN), eastwardness (AE), horizontal (or, tangential) curvature (k_h), vertical (or profile) curvature (k_v), difference curvature (E), horizontal excess curvature (k_{he}), vertical excess

Morphometry, Fig. 1 Example of basic morphometric variables for an alpine area (Trentino, Italy). (a) digital terrain model (pixel size 2 m); (b) shaded relief; (c) slope in degrees; (d) aspect classified in eight directions

(i.e., classes 45° degree wide); (e) profile curvature; (f) tangential curvature

Morphometry, Fig. 2 Examples of roughness indices (see Trevisani and Rocca 2015), based on a lag of 2 pixels and a circular moving window with a radius of 3 pixels, calculated for an alpine terrain (Trentino, Italy). (a) DTM and shaded relief (pixel size 2 m); (b)

isotropic roughness; (c) anisotropy in roughness (1 maximum anisotropy); (d) landscape classified according the ratio of isotropic roughness versus flow directional roughness: in green morphologies elongated in the direction of flow; in red morphologies elongated along contour lines

curvature (k_{ve}), accumulation curvature (K_a), ring curvature (K_r), rotor (rot), horizontal curvature deflection (D_{kh}), vertical curvature deflection (D_{kv}), and some others.

Local topographic variables are functions of the partial derivatives of elevation. In this regard, local variables can be divided into three groups: (1) first-order variables – G , A , AN , and AE – are functions of only the first derivatives; (2) second-order variables – k_{min} , k_{max} , H , K , M , ∇^2 , IS , C , k_h , k_v , E , k_{he} , k_{ve} , K_a , K_r , and rot – are functions of both the first and second derivatives; and (3) third-order variables –

D_{kh} and D_{kv} – are functions of the first, second, and third derivatives. Equations can be found elsewhere (Florinsky 2016, 2017).

The partial derivatives of elevation (and thus local morphometric variables) can be estimated from DEMs by (1) several finite-difference methods using 3×3 or 5×5 moving windows and (2) analytical computations based on DEM interpolation by local splines or global approximation of a DEM by high-order orthogonal polynomials.

Morphometry, Fig. 3 Schemes for the definitions of local, nonlocal, and two-field specific variables. (a) and (b) display two pairs of mutually perpendicular normal sections at a point P of the topographic surface: (a) Principal sections APA' and BPB'. (b) Sections CPC' and DPD' allocated by gravity. n is the external normal; g is the gravitational acceleration vector; cl is the contour line; sl is the slope line. (c) Catchment and

dispersive areas, CA and DA, are areas of figures P'AB (light gray) and P''AB (dark gray), correspondingly; b is the length of a contour line segment AB; l_1, l_2, l_3 , and l_4 are the lengths of slope lines P'A, P'B, AP'', and BP'', correspondingly. (d) The position of the Sun in the sky: θ is solar azimuth angle, ψ is solar elevation angle, and N is north direction. (From Florinsky (2017, Fig. 1))

Nonlocal Morphometric Variables

A nonlocal (or regional) morphometric variable is a single-valued bivariate function describing a relative position of a given point on the topographic surface.

Among nonlocal topographic variables are catchment area (CA) and dispersive area (DA). To determine nonlocal morphometric attributes, one should analyze a relatively large territory with boundaries located far away from a given point (e.g., an entire upslope portion of a watershed) (Fig. 3c).

Flow routing algorithms are usually applied to estimate nonlocal variables. These algorithms determine a route, along which a flow is distributed from a given point of the topographic surface to downslope points. There are several flow routing algorithms grouped into two types: (1) eight-node single-flow direction (D8) algorithms using one of the eight possible directions separated by 45° to model a flow from a given point and (2) multiple-flow direction (MFD) algorithms using the flow partitioning. There are some methods combining D8 and MFD principles.

Two-Field Specific Morphometric Variables

A two-field specific morphometric variable is a single-valued bivariate function describing relations between the topographic surface (located in gravity field) and other fields, in particular, solar irradiation and wind flow.

Among two-field specific morphometric variables are reflectance (R) and insolation (I). These variables are functions of the first partial derivatives of elevation and angles describing the position of the Sun in the sky (Fig. 3d). Reflectance and insolation can be derived from DEMs using methods for the calculation of local variables.

Combined Morphometric Variables

Morphometric variables can be composed from local and nonlocal variables. Such attributes consider both the local geometry of the topographic surface and a relative position of a point on the surface.

Among combined morphometric variables are topographic index (TI), stream power index (SI), and some others.

Combined variables are derived from DEMs by the sequential application of methods for nonlocal and local variables, followed by a combination of the results.

Conclusions

Geomorphometry is a discipline still in evolution and of growing interest in many applied and research contexts. Geomorphometry is a fundamental tool for studying geosphere-anthroposphere interlinked dynamics in the critical zone, especially when performing multitemporal morphometric analysis. Moreover, geomorphometric analysis permits to derive relevant geoenvironmental and hydrological parameters, useful for the numerical modelling of different processes such as floods, landslides, wildfires and ecological processes. Geomorphometric indices can be also exploited as secondary variables in various prediction approaches based on geostatistics or machine learning, for example for mapping soil properties. Geomorphometry is also adopted for the characterization of landscape and of geodiversity. Future developments in mathematical/computational approaches as well as in technology will likely amplify morphometry potentials.

Moving Average

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

A moving average is the mean or average of all values of a variable within a given domain that is moved across the space of study. Domain and space can be one-, two-, or three-dimensional. In Euclidian space, every moving average value is located at the center of its domain. For time series, the moving average can apply to values before the point in time at which it is located. In weighted moving average analysis, the values are assigned different weights usually decreasing with distance away from the point of location of each estimated moving average value.

Introduction

Along with “probability,” the mean or average is probably the best-known statistical tool. The first average on record was taken by William Borough in 1581 for a number of successive compass readings (*cf.* Eisenhart 1963; also see Hacking 2006). The procedure of averaging numbers was regarded with suspicion for a long time. Thomas Simpson (1755) advocated the approach in a paper entitled: “On the advantage of taking the mean of a number of observations in practical astronomy,” stating: “It is well-known that the method practiced by astronomers to diminish the errors arising from the imperfections of instrument and the organs of sense by taking the mean of several observations has not so generally been received but that some persons of note have publicly

maintained that one single observation, taken with due care, was as much to be relied on, as the mean of a great number.”

The simple, unweighted moving average of n values x_i within a given domain can be written as $\bar{x}_n = \frac{\sum_{i=1}^n x_i}{n}$. Different domains can have different values of n . An example is shown in Fig. 1. It is for a long series of 2796 copper (XRF) concentration values for cutting samples taken at 2 m intervals along the so-called Main KTB borehole of the German Continental Deep Drilling Program (abbreviated to KTB). These data are in the public domain (citation: KTB, WG Geochemistry). Depths of the first and last cuttings used for this series are 8 and 5596 m, respectively. Locally, in the database, results are reported for a 1-m sampling interval; then, alternate copper values at the standard 2 m interval were included in the series used, for example. Most values are shown in Fig. 1 together with a 101-point average representing consecutive 202-m log segments of drill-core. Locally, the original copper values deviate strongly from the moving average. It can be assumed that these deviations are largely random and that the moving average represents a reproducible copper concentration value contrary to the original XRF values that are subject to significant measurement errors.

Weighted Moving Average Methods

In most applications of the moving average method, different weights are assigned to the observed values depending on the distance between the point at which the moving average value

is to be calculated and the point at which a measurement is to be used. In time series analysis, more weight is commonly assigned to values at points in the more immediate past. A frequently used method in time series analysis is the exponentially weighted moving average (EWMA) method summarized by Hunter (1986) as follows: The predicted value at time $i + 1$ in a time series with observed values y_i can be written as $\hat{y}_{i+1} = \hat{y}_i + \lambda \epsilon_i$ where $0 < \lambda < 1$ is a constant and $\epsilon_i = y_i - \hat{y}_i$ is the observed random error at time i .

For applications in Euclidian space, more weight is assigned to values at points that are closer to the points at which the values are to be estimated. A well-known method in two-dimensional space consists of assigning weights to the observations that are inversely proportional to the squared distances between locations of the known values and location at which the value is to be estimated. An example from Cheng and Agterberg (2009) based on arsenic concentration values in about 1000 stream sediment samples in the Gejiu area in China is shown in Fig. 2a. This area contains large tin deposits in its southeastern part that have a long history of mining causing extensive pollution in the environment. The stream sediment sample locations were equally spaced at approximately 2 km in the north-south and east-west directions. Every sample represented a composite of materials from the drainage basin upstream of the collection site. In this application, each square on Fig. 2a represents the moving average for a square window measuring 26 km on a side with influence of samples decreasing according to the square of distance. For comparison, Fig. 2b also shows results of local singularity analysis applied to the same data set. This is a

Moving Average,

Fig. 1 Copper concentration (ppm) values from Main KTB bore-hole together with mean values for 101 m long segments of drill-core. Locally, the original data deviate strongly from the moving average. (Source: Agterberg 2014, Fig. 6.22)

Moving Average, Fig. 2 Map patterns derived from arsenic concentration values in stream sediment samples; triangles represent large tin mines rich in other elements including arsenic as well: (a) weighted moving average with weights inversely proportional to squared distance from point at which value is plotted; (b) local singularity based on small square cells with half-widths set equal to 1, 3, 5, ..., 13 km; for further explanation. (See Cheng and Agterberg 2009)

different contouring technique that places more emphasis on the strictly local environments of the points at which the average is to be computed (for details, see Cheng and Agterberg 2009). Obviously, the pattern of Fig. 2b is more advantageous when the objective is to find undiscovered mineral deposits in relatively unexplored target areas, because the areas used for the moving averaging are much larger in Fig. 2a.

One of the first applications of a weighted moving average technique in the geosciences is described in detail by Krige (1968) for gold assay values in South African gold mines. In this application, the weights were determined by the method of sampling that was applied to the gold deposits with more weight assigned to nearby sampling locations. Figure 3 (after

Krige 1966) shows two kinds of results for one particular gold mine although the same moving average method was applied. The area covered in Fig. 3b is 400 times as large as the area in Fig. 3a indicating scale independence (self-similarity) of the gold distribution pattern.

Other weighted moving average methods include hot spot analysis (see Getis and Ord 1992). It is widely applied by geographers to enhance two-dimensional patterns of random variables that exhibit spatial clustering. Typical examples are counts (x_{ij}) of occurrences (e.g., cases of a specific disease or accidents) for small areas (e.g., counties). Originally, the technique was based on Moran's I statistic for spatial correlation (Moran, 1968). It led to the Getis $G_i^*(d)$ statistic that satisfies:

Moving Average, Fig. 3 Typical gold inch-dwt weighted moving average trend surfaces in the Klerksdorp goldfield obtained on the basis of two-dimensional moving averages for two areas with similar average gold grades; value plotted is inch-pennyweight (1 unit = 3.95 cm-

g). (a) moving averages of 100×100 ft. areas within a mined-out section of 500×500 ft; (b) moving averages of 2000×2000 ft. areas within mined-out section of $10,000 \times 10,000$ ft. (Source: Krige 1966, Fig. 3)

$$G_i(d) = \frac{\sum_{j=1}^n w_{ij}(d)x_j}{\sum_{j=1}^n x_j}, j \text{ not equal to } i,$$

where $\{w_{ij}\}$ is an asymmetric one/zero spatial weight matrix with ones for all links defined as being within distance d of a given i , all other links being zero (cf. Getis and Ord 1992, p. 190). Setting $W_i = \sum_{j=1}^n w_{ij}(d)$, it can be shown that the expected value of $G_i(d)$ and its variance satisfy:

$$E[G_i(d)] = \frac{W_i}{n-1}; \sigma^2[G_i(d)] = \frac{W_i(n-1-W_i)Y_{i2}}{(n-1)^2(n-2)Y_{i1}^2}$$

where E denotes mathematical expectation and σ^2 is variance,

$$Y_{i1} = \frac{\sum_{j=1}^n x_j}{n-1}; \text{ and } Y_{i2} = \frac{\sum_{j=1}^n x_j^2}{n-1} - Y_{i1}^2.$$

For a one-dimensional application of hot-spot analysis, see Agterberg et al. (2020).

Summary and Conclusions

A moving average is the mean or average of all values of a variable within a given domain that is moved across its

Euclidian space of study. For time series, the moving average can apply to values before the point in time at which it is located. In weighted moving average analysis, the input values are assigned different weights, usually decreasing with distance away from the point of location of each estimated moving average value. By means of practical examples, it was shown in this entry that using the moving average can help to eliminate “noise” from the data. Also, applying weights to the observed values that decrease with distance away from each point, at which the moving average is estimated, often improves results. Further improvements may be obtainable when estimated average values are restricted to strictly local environments. The three examples (Figs. 1, 2 and 3) are concerned with element concentration values across study areas that exhibit scale-independence, which is documented in more detail in the original publications.

Multidimensional Scaling

Francky Fouedjio

Department of Geological Sciences, Stanford University,
Stanford, CA, USA

Definition

Multidimensional scaling (MDS) is a family of methods used for representing (dis)similarity measurements among objects (entities) as distances between points in a low-dimensional space, each point corresponding to one object (entity). MDS is concerned with the problem of constructing a configuration of n points in a m -dimensional space using information about the (dis)similarities between n objects, in such a way that inter-point distances reflect, in some sense, the (dis)similarities. Thus, similar objects are mapped close to each other, whereas dissimilar objects are located far apart.

Introduction

Multidimensional scaling (MDS) is frequently used in geosciences for exploring (dis)similarities among a set of

objects (entities) such as signals, images, simulations, predictions, or samples. The term “similarity” depicts the degree of likeness between two objects, while the term “dissimilarity” indicates the degree of unlikeness. Some objects are more dissimilar (or similar) to each other than others. For instance, colors red and pink are more similar (less dissimilar) to each other than colors red and green. Equivalently, colors red and green are more dissimilar (less similar) than colors red and pink. For dissimilarity data, a higher value indicates more dissimilar objects, while for similarity data, a higher value indicates more similar objects. Dissimilarities are distance-like quantities, while similarities are inversely related to distances. Dissimilarity or similarity information about a set of objects can arise in many different ways. For instance, if one considers an ensemble of continuous geostatistical realizations, the dissimilarity between any two realizations can be defined as the square root sum of square differences between realizations, which is calculated cell-by-cell.

Multidimensional scaling (MDS) aims to map objects’ relative location using data that show how these objects are dissimilar or similar. The basic idea consists of representing the objects in a low-dimensional space (usually Euclidean) so that the inter-point distances best agree with the observed (dis)similarities between the objects. In other words, MDS depicts interobject (dis)similarities by inter-point distances, each point corresponding to one object. In this way, MDS provides interpretable graphical displays (i.e., maps of objects), in which dissimilar objects are located far apart, and similar objects are mapped close to each other. In the color example, the points representing red and pink will be located closer in the space than the points representing red and green. MDS’s map facilitates our intuitive understanding of the relationships among the objects represented in the map. It helps to understand and possibly explain any structure or pattern in the data.
